## Chapter 1

## Introduction

This is the RISC-V Bitmanip Extension draft spec.

## 1.1 ISA Extension Proposal Design Criteria

Any proposed changes to the ISA should be evaluated according to the following criteria.

- Architecture Consistency: Decisions must be consistent with RISC-V philosophy. ISA changes should deviate as little as possible from existing RISC-V standards (such as instruction encodings), and should not re-implement features that are already found in the base specification or other extensions.
- Threshold Metric: The proposal should provide *significant* savings in terms of clocks or instructions. As a heuristic, any proposal should replace at least three instructions. An instruction that only replaces two may be considered, but only if the frequency of use is very high and/or the implementation very cheap.
- Data-Driven Value: Usage in real world applications, and corresponding benchmarks showing a performance increase, will contribute to the score of a proposal. A proposal will not be accepted on the merits of its *theoretical* value alone, unless it is used in the real world.
- Hardware Simplicity: Though instructions saved is the primary benefit, proposals that dramatically increase the hardware complexity and area, or are difficult to implement, should be penalized and given extra scrutiny. The final proposals should only be made if a test implementation can be produced.
- Compiler Support: ISA changes that can be natively detected by the compiler, or are already used as intrinsics, will score higher than instructions which do not fit that criteria.

### 1.2 B Extension Adoption Strategy

The overall goal of this extension is pervasive adoption by minimizing potential barriers and ensuring the instructions can be mapped to the largest number of ops, either direct or pseudo, that are supported by the most popular processors and compilers. By adding generic instructions and taking advantage of the RISC-V base instructions that already operate on bits, the minimal set of instructions need to be added while at the same time enabling a rich of operations.

The instructions cover the four major categories of bit manipulation: Count, Extract, Insert, Swap. The spec supports RV32, RV64, and RV128. "Clever" obscure and/or overly specific instructions are avoided in favor of more straightforward, fast, generic ones. Coordination with other emerging RISC-V ISA extensions groups is required to ensure our instruction sets are architecturally consistent.

### 1.3 Next steps

- Assign concrete instruction encodings so that we can start implementing the extension in processor cores and compilers.
- Add support for this extension to processor cores and compilers so we can run quantitative evaluations on the instructions.
- Create assembler snippets for common operations that do not map 1:1 to any instruction in this spec, but can be implemented easily using clever combinations of the instructions. Add support for those snippets to compilers.

## Chapter 2

# RISC-V Bitmanip Extension

In the proposals provided in this chapter, the C code examples are for illustration purposes only. They are not optimal implementations, but are intended to specify the desired functionality.

The final standard will likely define a range of Z-extensions for different bit manipulation instructions, with the "B" extension itself being a mix of instructions from those Z-extensions. It is unclear as of yet what this will look like exactly, but it will probably look something like this:

	B?		
Zbb? (base)	<pre>clz, ctz, pcnt slo[i], sro[i] min[u], max[u] add[i]wu, subwu addu.w, subu.w slliu.w</pre>	<pre>sbset[i] sbclr[i] sbinv[i] sbext[i]</pre>	Zbs (single bit)
	andn, orn xnor, pack[hu] rol, ror[i] rev8, rev orc.b	grev[i] gorc[i] [un]shfl[i]	Zbp (permutation)
Zbe	bext, bdep	bfp	Zbf
Zbc	clmul[hr]	crc32[c]	${f Z}{f br}$
Zbm (matrix)	<pre>bmat[x]or bmatflip</pre>	<pre>cmov, cmix fsl, fsr[i]</pre>	Zbt (ternary)

The main open questions of course relate to what should and shouldn't be included in "B", and

what should or shouldn't be included in "Zbb". These decisions will be informed in big part by evaluations of the cost and added value for the individual instructions.

The main open questions are:

- Should clmul [hr] be included in "B", or crc32. [bhwd]/crc32c. [bhwd], or neither, or both?
- Should "Zbe" be included in "B"? Should "Zbm be included in "B"?
- Which "Zbp" pseudo-ops should be included in "B"? Which in "Zbb"? Should "Zbp" be included in "B" as a whole?

For the purpose of tool-chain development "B" is currently everything.

For extensions that only implement certain pseudo-instructions (such as "Zbb" implements rev8 and rev, which are pseudo-instructions for grevi rd, rs1, -8 and grevi rd, rs1, -1 respectively, the same binary encoding is used for those instructions as are used on a core with full support for the grev[i] instruction.

Like in the base ISA, we add \*W instruction variants on RV64 with the semantic of the matching RV32 instruction. Those instructions ignore the upper 32 bit of their input and sign-extend their 32 bit output values. The \*W instruction is omitted when the 64-bit instruction produces the same result as the \*W instruction would when the 64-bit instruction is fed sign-extended 32 bit values.

## 2.1 Basic bit manipulation instructions

#### 2.1.1 Count Leading/Trailing Zeros (clz, ctz)

```
RV32, RV64:
clz rd, rs
ctz rd, rs
RV64 only:
clzw rd, rs
ctzw rd, rs
```

The clz operation counts the number of 0 bits at the MSB end of the argument. That is, the number of 0 bits before the first 1 bit counting from the most significant bit. If the input is 0, the output is XLEN. If the input is -1, the output is 0.

The ctz operation counts the number of 0 bits at the LSB end of the argument. If the input is 0, the output is XLEN. If the input is -1, the output is 0.

```
uint_xlen_t clz(uint_xlen_t rs1)
{
    for (int count = 0; count < XLEN; count++)
        if ((rs1 << count) >> (XLEN - 1))
            return count;
    return XLEN;
}
uint_xlen_t ctz(uint_xlen_t rs1)
{
    for (int count = 0; count < XLEN; count++)
        if ((rs1 >> count) & 1)
            return count;
    return XLEN;
}
```

The expression XLEN-1-clz(x) evaluates to the index of the most significant set bit, also known as integer base-2 logarithm, or -1 if x is zero.

These instructions are commonly used for scanning bitmaps for set bits, for example in malloc(), in binary GCD, or in priority queues such as the sched\_find\_first\_bit() function used in the Linux kernel real-time scheduler.

Another common applications include normalization in fixed-point code and soft float libraries, null suppression in data compression.

#### 2.1.2 Count Bits Set (pcnt)

```
RV32, RV64:
pcnt rd, rs

RV64 only:
pcntw rd, rs
```

This instruction counts the number of 1 bits in a register. This operations is known as population count, popcount, sideways sum, bit summation, or Hamming weight. [22, 20]

```
uint_xlen_t pcnt(uint_xlen_t rs1)
{
   int count = 0;
   for (int index = 0; index < XLEN; index++)
        count += (rs1 >> index) & 1;
   return count;
}
```

#### 2.1.3 Logic-with-negate (andn, orn, xnor)

```
RV32, RV64:
andn rd, rs1, rs2
orn rd, rs1, rs2
xnor rd, rs1, rs2
```

This instructions implement AND, OR, and XOR with the 2nd arument inverted.

```
uint_xlen_t andn(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return rs1 & ~rs2;
}
uint_xlen_t orn(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return rs1 | ~rs2;
}
uint_xlen_t xnor(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return rs1 ^ ~rs2;
}
```

This can use the existing inverter on rs2 in the ALU that's already there to implement subtract.

Among other things, those instructions allow implementing the "trailing bit manipulation" code patterns in two instructions each. For example, (x - 1) & x produces a mask from trailing zero bits in x.

#### 2.1.4 Pack two words in one register (pack, packu, packh)

```
RV32, RV64:

pack rd, rs1, rs2
packu rd, rs1, rs2
packh rd, rs1, rs2

RV64 only:
packw rd, rs1, rs2
packuw rd, rs1, rs2
packuw rd, rs1, rs2
```

The pack instruction packs the XLEN/2-bit lower halves of rs1 and rs2 into rd, with rs1 in the lower half and rs2 in the upper half.

```
uint_xlen_t pack(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t lower = (rs1 << XLEN/2) >> XLEN/2;
    uint_xlen_t upper = rs2 << XLEN/2;
    return lower | upper;
}</pre>
```

The packu instruction packs the upper halves of rs1 and rs2 into rd.

```
uint_xlen_t packu(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t lower = rs1 >> XLEN/2;
    uint_xlen_t upper = (rs2 >> XLEN/2) << XLEN/2;
    return lower | upper;
}</pre>
```

And the packh instruction packs the LSB bytes of rs1 and rs2 into the 16 LSB bits of rd, zero extending the rest of rd.

```
uint_xlen_t packh(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t lower = rs1 & 255;
    uint_xlen_t upper = (rs2 & 255) << 8;
    return lower | upper;
}</pre>
```

Applications include XLEN/2-bit funnel shifts, zero-extend XLEN/2 bit values, duplicate the lower XLEN/2 bits (e.g. for mask creation), loading unsigned 32 constants on RV64, and packing C structs that fit in a register and are therefore passed in a register according to the RISC-V calling convention.

```
; Constructing a 32-bit int from four bytes (RV32) packh a0, a0, a1 packh a1, a2, a3 pack a0, a0, a1 ; Load Oxffff00000ffff0000 on RV64 lui rd, Oxffff0 pack rd, rd, rd ; Same as FSLW on RV64 pack rd, rs1, rs3 rol rd, rd, rs2 addiw rd, rd, 0 ; Clear the upper half of rd pack rd, rd, zero
```

Paired with shfli/unshfli and the other bit permutation instructions, pack can interleave arbitrary power-of-two chunks of rs1 and rs2. For example, interleaving the bytes in the lower halves of rs1 and rs2:

```
pack rd, rs1, rs2
zip8 rd, rd
```

pack is most commonly used to zero-extend words <XLEN. For this purpose we define the following assembler pseudo-ops:

```
RV32:
 zext.b rd, rs
                 ->
                      andi rd, rs, 255
 zext.h rd, rs
                 ->
                      pack rd, rs, zero
RV64:
 zext.b rd, rs
                 ->
                    andi rd, rs, 255
 zext.h rd, rs
                      packw rd, rs, zero
               ->
 zext.w rd, rs
               ->
                      pack rd, rs, zero
RV128:.
 zext.b rd, rs
               ->
                      andi rd, rs, 255
 zext.h rd, rs
               ->
                      packw rd, rs, zero
 zext.w rd, rs ->
                    packd rd, rs, zero
 zext.d rd, rs ->
                      pack rd, rs, zero
```

#### 2.1.5 Min/max instructions (min, max, minu, maxu)

```
RV32, RV64:
min rd, rs1, rs2
max rd, rs1, rs2
minu rd, rs1, rs2
maxu rd, rs1, rs2
maxu rd, rs1, rs2
```

We define 4 R-type instructions min, max, minu, maxu with the following semantics:

```
uint_xlen_t min(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return (int_xlen_t)rs1 < (int_xlen_t)rs2 ? rs1 : rs2;
}
uint_xlen_t max(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return (int_xlen_t)rs1 > (int_xlen_t)rs2 ? rs1 : rs2;
}
uint_xlen_t minu(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return rs1 < rs2 ? rs1 : rs2;
}</pre>
```

```
uint_xlen_t maxu(uint_xlen_t rs1, uint_xlen_t rs2)
{
    return rs1 > rs2 ? rs1 : rs2;
}
```

Code that performs saturated arithmetic on a word size < XLEN needs to perform min/max operations frequently. A simple way of performing those operations without branching can benefit those programs.

Some applications spend a lot of time on calculating the absolute values of signed integers. One example of that would be SAT solvers, due to the way CNF literals are commonly encoded [10]. With max (or minu) this is a two-instruction operation:

```
neg a1, a0
max a0, a0, a1
```

#### 2.1.6 Single-bit instructions (sbset, sbclr, sbinv, sbext)

```
🗕 RISC-V Bitmanip ISA 🗕
RV32, RV64:
 sbset rd, rs1, rs2
 sbclr rd, rs1, rs2
 sbinv rd, rs1, rs2
 sbext rd, rs1, rs2
 sbseti rd, rs1, imm
  sbclri rd, rs1, imm
  sbinvi rd, rs1, imm
  sbexti rd, rs1, imm
RV64:
 sbsetw rd, rs1, rs2
 sbclrw rd, rs1, rs2
 sbinvw rd, rs1, rs2
  sbextw rd, rs1, rs2
  sbsetiw rd, rs1, imm
  sbclriw rd, rs1, imm
  sbinviw rd, rs1, imm
```

We define 4 single-bit instructions sbset (set), sbclr (clear), sbinv (invert), and sbext (extract), and their immediate-variants, with the following semantics:

```
uint_xlen_t sbset(uint_xlen_t rs1, uint_xlen_t rs2)
{
   int shamt = rs2 & (XLEN - 1);
   return rs1 | (uint_xlen_t(1) << shamt);
}</pre>
```

```
uint_xlen_t sbclr(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return rs1 & ~(uint_xlen_t(1) << shamt);
}
uint_xlen_t sbinv(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return rs1 ^ (uint_xlen_t(1) << shamt);
}
uint_xlen_t sbext(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return 1 & (rs1 >> shamt);
}
```

#### 2.1.7 Shift Ones (Left/Right) (slo, sloi, sro, sroi)

```
RV32, RV64:
slo rd, rs1, rs2
sro rd, rs1, imm
sroi rd, rs1, imm

RV64 only:
slow rd, rs1, rs2
srow rd, rs1, rs2
sloiw rd, rs1, rs2
sloiw rd, rs1, imm
sroiw rd, rs1, imm
```

These instructions are similar to shift-logical operations from the base spec, except instead of shifting in zeros, they shift in ones.

```
uint_xlen_t slo(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return ~(~rs1 << shamt);
}
uint_xlen_t sro(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return ~(~rs1 >> shamt);
}
```

ISAs with flag registers often have a "Shift in Carry" or "Rotate through Carry" instruction.

Arguably a "Shift Ones" is an equivalent on an ISA like RISC-V that avoids such flag registers.

The main application for the Shift Ones instruction is mask generation.

When implementing this circuit, the only change in the ALU over a standard logical shift is that the value shifted in is not zero, but is a 1-bit register value that has been forwarded from the high bit of the instruction decode. This creates the desired behavior on both logical zero-shifts and logical ones-shifts.

### 2.2 Bit permutation instructions

The following sections describe 3 types of bit permutation instructions: Rotate shift, generalized reverse, and generalized shuffle.

A bit permutation essentially is applying an invertible function to the bit addresses. (Bit addresses are 5 bit values on RV32 and 6 bit values on RV64.)

Rotate shift by k is simply addition (rol) or subtraction (ror) modulo XLEN.

$$i'_{\text{rot}} := i \pm k \mod XLEN$$

Generalized reverse with control argument k is simply XOR-ing the bit addresses with k:

$$i'_{ ext{grev}} := i \oplus k$$

And generalized shuffle is performing a bit permutation on the bits of the bit addresses:

$$i'_{\text{shfl}} := \text{perm}_k(i)$$

With the caveat that a single shfl/unshfl instruction can only perferm a certain sub-set of bit address permutations, but a sequence of 4 shfl/unshfl instructions can perform any of the 120 such permutations on RV32, and a sequence of 5 shfl/unshfl instructions can perform any of the 720 such permutations on RV64.

Combining those three types of operations makes a vast number of bit permutations accessible within only a few instructions [24] (see Table 2.1).

Sequences of ror, grev, and [un]shfl instructions can generate any arbitrary bit permutation. Often in surprising ways. For example, the following sequence swaps the two LSB bits of a0:

```
rori a0, a0, 2
unshfli a0, a0, -1
roli a0, a0, 1
shfli a0, a0, -1
```

The mechanics of this sequence is closely related to the fact that rol(ror(x-2)+1) is a function that maps 1 to 0 and 0 to 1 and every other number to itself. (With rol and ror denoting 1-bit rotate left and right shifts respectively.) See Table 2.2 for details.

N	ROT-only	GREV-only	SHFL-only	ROT+GREV	ROT+GREV+SHFL
0	1	1	1	1	1
1	32	32	24	62	85
2			86	864	3030
3			119	4640	78659
4			120	23312	2002167
5				92192	50106844
6				294992	1234579963
7				703744	est. $30000000000$
8				1012856	est. $700000000000$
9				1046224	est. $15000000000000$
10				1048576	
11	_				

Table 2.1: Number of permutations reachable with N permutation instructions on RV32. "—" indicates that additional instructions don't increase the space of reachable permutations.

Instruction	State (XLEN=8)	Bit-Index Op
initial value	7 6 5 4 3 2 1 0	<u> </u>
rori a0, a0, 2	$1\ 0\ 7\ 6\ 5\ 4\ 3\ 2$	i' := i - 2
unshfli a0, a0, -1	$1\ 7\ 5\ 3\ 0\ 6\ 4\ 2$	i' := ror(i)
roli a0, a0, 1	7 5 3 0 6 4 2 1	i' := i + 1
shfli a0, a0, -1	$7\ 6\ 5\ 4\ 3\ 2\ 0\ 1$	$i' := \operatorname{rol}(i)$

Table 2.2: Breakdown of the ror+[un]shfl sequence for swapping the two LSB bits of a word, using XLEN=8 for simplicity.

There are 24 ways of arranging the four bytes in a 32-bit word. ror, grev, and [un]shfl can perform any of those permutations in at most 3 instructions. See Table 4.1 for a list of those 24 sequences.

There are 40320 ways of arranging the eight bytes in a 64-bit word or the eight nibbles in a 32-bit word. ror, grev, and [un]shfl can perform any of those permutations in at most 9 instructions. [24]

#### 2.2.1 Rotate (Left/Right) (rol, ror, rori)

```
RV32, RV64:
ror rd, rs1, rs2
rol rd, rs1, imm

RV64 only:
rorw rd, rs1, rs2
rolw rd, rs1, rs2
roriw rd, rs1, rs2
roriw rd, rs1, imm
```

These instructions are similar to shift-logical operations from the base spec, except they shift in the values from the opposite side of the register, in order. This is also called 'circular shift'.

```
uint_xlen_t rol(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return (rs1 << shamt) | (rs1 >> ((XLEN - shamt) & (XLEN - 1)));
}
uint_xlen_t ror(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int shamt = rs2 & (XLEN - 1);
    return (rs1 >> shamt) | (rs1 << ((XLEN - shamt) & (XLEN - 1)));
}</pre>
```

#### 2.2.2 Generalized Reverse (grev, grevi, rev)

```
RV32, RV64:
grev rd, rs1, rs2
grevi rd, rs1, imm

RV64 only:
grevw rd, rs1, rs2
greviw rd, rs1, imm
```

This instruction provides a single hardware instruction that can implement all of byte-order swap, bitwise reversal, short-order-swap, word-order-swap (RV64), nibble-order swap, bitwise reversal in a byte, etc, all from a single hardware instruction.

The Generalized Reverse (GREV) operation iteratively checks each bit i in the 2nd argument from i = 0 to  $log_2(XLEN) - 1$ , and if the corresponding bit is set, swaps each adjacent pair of  $2^i$  bits.

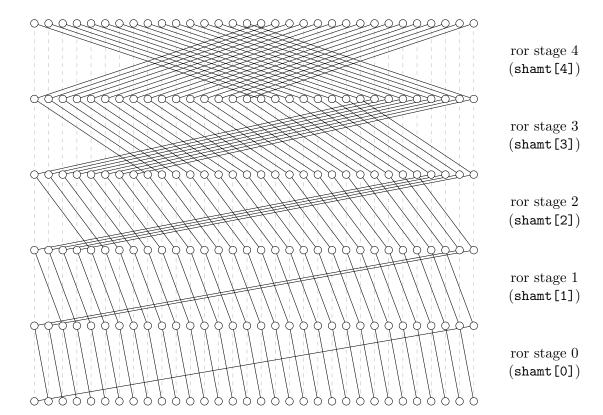

Figure 2.1: ror permutation network

```
uint32_t grev32(uint32_t rs1, uint32_t rs2)
{
    uint32_t x = rs1;
    int shamt = rs2 & 31;
    if (shamt & 1) x = ((x & 0x555555555) << 1) | ((x & 0xAAAAAAAA) >> 1);
    if (shamt & 2) x = ((x & 0x333333333) << 2) | ((x & 0xCCCCCCCC) >> 2);
    if (shamt & 4) x = ((x & 0x0F0F0F0F) << 4) | ((x & 0xF0F0F0F0) >> 4);
    if (shamt & 8) x = ((x & 0x00FF00FF) << 8) | ((x & 0xFF00FF00) >> 8);
    if (shamt & 16) x = ((x & 0x0000FFFF) << 16) | ((x & 0xFFFF0000) >> 16);
    return x;
}
```

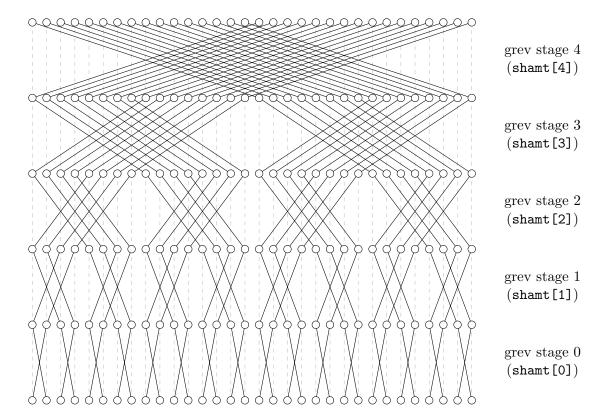

Figure 2.2: grev permutation network

```
uint64_t grev64(uint64_t rs1, uint64_t rs2)
   uint64_t x = rs1;
   int shamt = rs2 \& 63;
   1);
   if (shamt & 2) x = ((x \& 0x33333333333333333)) <<
                                                2) |
                    ((x & 0xCCCCCCCCCCCLL) >>
   if (shamt & 4) x = ((x & 0x0F0F0F0F0F0F0F0FLL) <<
                                               4) l
                    ((x & 0xF0F0F0F0F0F0F0F0LL) >>
                                                4);
   if (shamt & 8) x = ((x & 0x00FF00FF00FF00FFLL) <<
                                                8) |
                    ((x & 0xFF00FF00FF00LL) >> 8);
   if (shamt & 16) x = ((x & 0x0000FFFF0000FFFFLL) << 16) |
                     ((x & 0xFFFF0000FFFF0000LL) >> 16);
   if (shamt & 32) x = ((x \& 0x00000000FFFFFFFFLL) << 32) |
                    ((x & 0xFFFFFFF00000000LL) >> 32);
   return x;
}
```

The above pattern should be intuitive to understand in order to extend this definition in an obvious manner for RV128.

The grev operation can easily be implemented using a permutation network with  $log_2(XLEN)$

Table 2.3: Pseudo-instructions for grevi instruction

stages. Figure 2.1 shows the permutation network for ror for reference. Figure 2.2 shows the permutation network for grev.

Pseudo-instructions are provided for the most common GREVI use-cases. Their names consist of a prefix and and optional suffix. Each prefix and suffix corresponds to a bit mask (see Table 2.4). The GREVI control word is obtained by AND-ing the two masks together.

In other words, the prefix controls the number of zero bits at the LSB end of the control word, and the suffix controls the number of zeros at the MSB end of the control word.

rev8 reverses the order of bytes in a word, thus performs endianness conversion. This is equivalent to the ARM REV instructions or BSWAP on x86. ARM also has instructions for swapping the bytes in 16-bit and 32-bit words, and reversing the bit order (see table 2.5).

Prefix	Mask	Suffix	Mask	
rev	111111		111111	
rev2	111110	.W	011111	(w = word)
rev4	111100	.h	001111	(h = half word)
rev8	111000	.b	000111	(b = byte)
rev16	110000	.n	000011	(n = nibble)
rev32	100000	.p	000001	(p = pair)

Table 2.4: Naming scheme for grevi pseudo-instructions. The prefix and suffix masks are ANDed to compute the immediate argument.

Table 2.5: Comparison of bit/byte reversal instructions

#### 2.2.3 Generalized Shuffle (shfl, unshfl, shfli, unshfli, zip, unzip)

```
RISC-V Bitmanip ISA

RV32, RV64:
shfl rd, rs1, rs2
unshfl rd, rs1, imm
unshfli rd, rs1, imm

RV64 only:
shflw rd, rs1, rs2
unshflw rd, rs1, rs2
unshflw rd, rs1, rs2
```

Shuffle is the third bit permutation instruction in the RISC-V Bitmanip extension, after rotary shift and generalized reverse. It implements a generalization of the operation commonly known as perfect outer shuffle and its inverse (shuffle/unshuffle), also known as zip/unzip or interlace/uninterlace.

Bit permutations can be understood as reversible functions on bit indices (i.e. 5 bit functions on RV32 and 6 bit functions on RV64).

Operation	Corresponding function on bit indices
Rotate shift	Addition modulo XLEN
Generalized reverse	XOR with bitmask
Generalized shuffle	Bitpermutation

A generalized (un)shuffle operation has  $log_2(XLEN) - 1$  control bits, one for each pair of neighbouring bits in a bit index. When the bit is set, generalized shuffle will swap the two index bits.

The shf1 operation performs this swaps in MSB-to-LSB order (performing a rotate left shift on contiguous regions of set control bits), and the unshf1 operation performs the swaps in LSB-to-MSB order (performing a rotate right shift on contiguous regions of set control bits). Combining up to  $log_2(XLEN)$  of those shf1/unshf1 operations can implement any bitpermutation on the bit indices.

The most common type of shuffle/unshuffle operation is one on an immediate control value that only contains one contiguous region of set bits. We call those operations zip/unzip and provide pseudo-instructions for them. The naming scheme for those pseudo-instructions is similar to the naming scheme for the grevi pseudo-instructions (see Tables 2.3 and 2.4), except that the LSB bit of the masks in Table 2.4 is not used for zip/unzip.

Shuffle/unshuffle operations that only have individual bits set (not a contiguous region of two or more bits) are their own inverse.

					=

Table 2.7: RV64 modes and pseudo-instructions for shfli/unshfli instruction

of elementary permutations, that are enabled or disabled by the shamt bits. But (un)shuffle has one stage fewer than GREV. Thus shfli+unshfli together require the same amount of encoding space as grevi.

```
uint32_t shuffle32_stage(uint32_t src, uint32_t maskL, uint32_t maskR, int N)
{
    uint32_t x = src & ~(maskL | maskR);
    x |= ((src << N) & maskL) | ((src >> N) & maskR);
    return x;
}
```

Or for RV64:

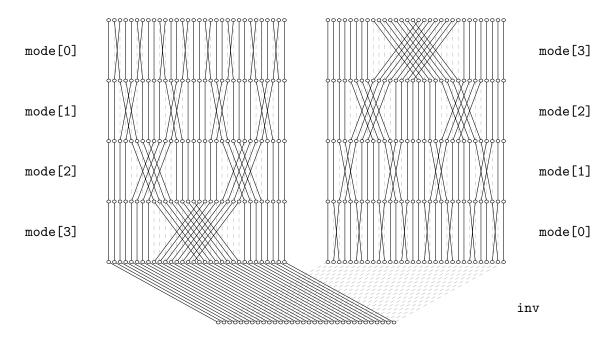

Figure 2.3: (un)shuffle permutation network without "flip" stages

```
uint32_t shf132(uint32_t rs1, uint32_t rs2)
{
    uint32_t x = rs1;
    int shamt = rs2 & 15;
    if (shamt & 8) x = shuffle32\_stage(x, 0x00ff0000, 0x0000ff00, 8);
    if (shamt & 4) x = shuffle32\_stage(x, 0x0f000f00, 0x00f000f0, 4);
    if (shamt & 2) x = shuffle32\_stage(x, 0x30303030, 0x0c0c0c0c, 2);
    if (shamt & 1) x = shuffle32\_stage(x, 0x44444444, 0x222222222, 1);
    return x;
}
uint32_t unshf132(uint32_t rs1, uint32_t rs2)
{
    uint32_t x = rs1;
    int shamt = rs2 \& 15;
    if (shamt & 1) x = shuffle32\_stage(x, 0x44444444, 0x222222222, 1);
    if (shamt & 2) x = shuffle32_stage(x, 0x30303030, 0x0c0c0c0c, 2);
    if (shamt & 4) x = shuffle32_stage(x, 0x0f000f00, 0x00f000f0, 4);
    if (shamt & 8) x = shuffle32\_stage(x, 0x00ff0000, 0x0000ff00, 8);
    return x;
}
```

```
uint64_t shuffle64_stage(uint64_t src, uint64_t maskL, uint64_t maskR, int N)
{
   uint64_t x = src & ~(maskL | maskR);
   x \mid = ((src \ll N) \& maskL) \mid ((src >> N) \& maskR);
   return x;
}
uint64_t shf164(uint64_t rs1, uint64_t rs2)
   uint64_t x = rs1;
   int shamt = rs2 \& 31;
   if (shamt & 16) x = shuffle64_stage(x, 0x0000ffff00000000LL,
                                       0x0000000ffff0000LL, 16);
   if (shamt & 8) x = shuffle64_stage(x, 0x00ff000000ff0000LL,
                                       0x0000ff000000ff00LL, 8);

                                       0x00f000f000f000f0LL, 4);
   if (shamt & 2) x = shuffle64_stage(x, 0x303030303030303030LL,
                                       0x0c0c0c0c0c0c0c0cLL, 2);
   0x222222222222LL, 1);
   return x;
}
uint64_t unshf164(uint64_t rs1, uint64_t rs2)
{
   uint64_t x = rs1;
   int shamt = rs2 \& 31;
   0x222222222222LL, 1);
   if (shamt & 2) x = shuffle64\_stage(x, 0x303030303030303030LL,
                                       0x0c0c0c0c0c0c0c0cLL, 2);
   if (shamt & 4) x = shuffle64\_stage(x, 0x0f000f000f000f000LL),
                                       0x00f000f000f00LL, 4);
   if (shamt & 8) x = shuffle64\_stage(x, 0x00ff000000ff00000LL,
                                       0x0000ff000000ff00LL, 8);
   if (shamt & 16) x = shuffle64\_stage(x, 0x0000ffff00000000LL,
                                       0x0000000ffff0000LL, 16);
   return x;
}
```

The above pattern should be intuitive to understand in order to extend this definition in an obvious manner for RV128.

Alternatively (un)shuffle can be implemented in a single network with one more stage than GREV,

with the additional first and last stage executing a permutation that effectively reverses the order of the inner stages. However, since the inner stages only mux half of the bits in the word each, a hardware implementation using this additional "flip" stages might actually be more expensive than simply creating two networks.

```
uint32_t shuffle32_flip(uint32_t src)
{
    uint32_t x = src & 0x88224411;
    x = ((src << 6) \& 0x22001100) | ((src >> 6) \& 0x00880044);
    x = ((src \ll 9) \& 0x00440000) | ((src >> 9) \& 0x00002200);
    x = ((src \ll 15) \& 0x44110000) | ((src >> 15) \& 0x00008822);
    x = ((src \ll 21) \& 0x11000000) | ((src >> 21) \& 0x00000088);
    return x;
}
uint32_t unshf132alt(uint32_t rs1, uint32_t rs2)
{
    uint32_t shfl_mode = 0;
    if (rs2 & 1) shfl_mode |= 8;
    if (rs2 & 2) shfl_mode |= 4;
    if (rs2 & 4) shfl_mode |= 2;
    if (rs2 & 8) shfl_mode |= 1;
    uint32_t x = rs1;
    x = shuffle32_flip(x);
    x = shf132(x, shfl_mode);
    x = shuffle32_flip(x);
    return x;
}
```

Figure 2.4 shows the (un)shuffle permutation network with "flip" stages and Figure 2.3 shows the (un)shuffle permutation network without "flip" stages.

The **zip** instruction with the upper half of its input cleared performs the commonly needed "fanout" operation. (Equivalent to **bdep** with a 0x55555555 mask.) The **zip** instruction applied twice fans out the bits in the lower quarter of the input word by a spacing of 4 bits.

For example, the following code calculates the bitwise prefix sum of the bits in the lower byte of a 32 bit word on RV32:

```
andi a0, a0, 0xff
zip a0, a0
zip a0, a0
slli a1, a0, 4
c.add a0, a1
slli a1, a0, 8
c.add a0, a1
slli a1, a0, 16
c.add a0, a1
```

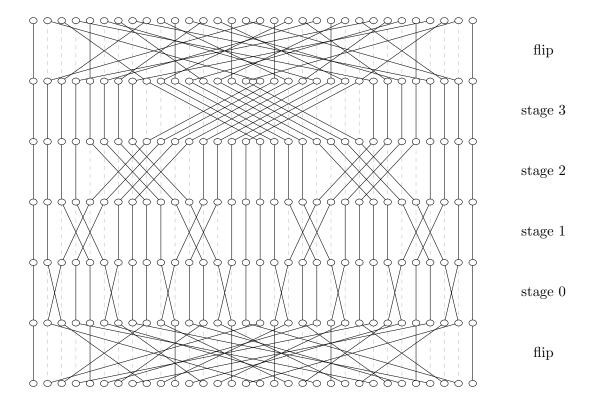

Figure 2.4: (un)shuffle permutation network with "flip" stages

The final prefix sum is stored in the 8 nibbles of the a0 output word.

Similarly, the following code stores the indices of the set bits in the LSB nibbles of the output word (with the LSB bit having index 1), with the unused MSB nibbles in the output set to zero:

```
andi a0, a0, 0xff
zip a0, a0
zip a0, a0
orc.n a0, a0
li a1, 0x87654321
and a1, a0, a1
bext a0, a1, a0
```

Other zip modes can be used to "fan-out" in blocks of 2, 4, 8, or 16 bit. zip can be combined with grevi to perform inner shuffles. For example on RV64:

```
li a0, 0x0000000012345678

zip4 t0, a0 ; <- 0x0102030405060708

rev4.b t1, t0 ; <- 0x1020304050607080

zip8 t2, a0 ; <- 0x00120034005600780

rev8.h t3, t2 ; <- 0x1200340056007800

zip16 t4, a0 ; <- 0x0000123400005678

rev16.w t5, t4 ; <- 0x1234000056780000
```

Another application for the zip instruction is generating Morton code [23].

The x86 PUNPCK [LH] \*  $\rm MMX/SSE/AVX$  instructions perform similar operations as zip8 and zip16.

Table 2.8: Pseudo-instructions for gorci instruction

## 2.3 Generalized OR-Combine (gorc, gorci)

```
RISC-V Bitmanip ISA

gorc rd, rs1, rs2
gorci rd, rs1, imm

RV64 only:
gorcw rd, rs1, rs2
gorciw rd, rs1, imm
```

The GORC operation is similar to GREV, except that instead of swapping pairs of bits, GORC ORs them together, and writes the new value in both positions.

```
uint32_t gorc32(uint32_t rs1, uint32_t rs2)
{
   uint32_t x = rs1;
   int shamt = rs2 \& 31;
   if (shamt & 1) x = ((x & 0x555555555) << 1) | ((x & 0xAAAAAAAA) >> 
                                                                   1);
   if (shamt & 2) x |= ((x & 0x33333333) << 2) | ((x & 0xCCCCCCCC) >>
                                                                   2);
   if (shamt & 4) x |= ((x & 0x0F0F0F0F) << 4) | ((x & 0xF0F0F0F0) >>
                                                                   4);
   if (shamt & 8) x |= ((x & 0x00FF00FF) << 8) | ((x & 0xFF00FF00) >>
                                                                   8);
   if (shamt & 16) x |= ((x & 0x0000FFFF) << 16) | ((x & 0xFFFF0000) >> 16);
   return x;
}
uint64_t gorc64(uint64_t rs1, uint64_t rs2)
{
   uint64_t x = rs1;
   int shamt = rs2 \& 63;
   1) |
                       ((x & Oxaaaaaaaaaaaaaaall) >>
                                                    1);
   2) |
                      ((x & 0xCCCCCCCCCCCCLL) >>
                                                   2);
   if (shamt & 4) x |= ((x & 0x0F0F0F0F0F0F0F0FLL) <<
                                                   4) |
                       ((x & 0xF0F0F0F0F0F0F0F0LL) >>
                                                   4);
   if (shamt & 8) x = ((x & 0x00FF00FF00FF00FFLL) <<
                                                   8) |
                      ((x & 0xFF00FF00FF00LL) >>
                                                   8);
   if (shamt & 16) x |= ((x & 0x0000FFFF0000FFFFLL) << 16) |
                      ((x & 0xFFFF0000FFFF0000LL) >> 16);
   if (shamt & 32) x |= ((x & 0x00000000FFFFFFFLL) << 32) |
                      ((x & 0xFFFFFFF00000000LL) >> 32);
   return x;
}
```

GORC can be usefull for copying naturally aligned fields in a word, and testing such fields for being equal zero.

gorci pseudo-instructions follow the same naming scheme as grevi pseudo-instructions (see Tables 2.3 and 2.4), except the prefix orc is used instead of rev. See Table 2.8 for a full list of gorci pseudo-instructions.

An important use-case is strlen() and strcpy(), which can utilize orc.b for testing for zero bytes, and counting trailing non-zero bytes in a word.

## 2.4 Bit-Field Place (bfp)

```
RV32, RV64:
bfp rd, rs1, rs2

RV64 only:
bfpw rd, rs1, rs2
```

The bit field place (bfp) instruction places up to 16 LSB bit from rs2 into the value in rs1. The upper bits of rs2 control the length of the bit field and target position.

```
uint_xlen_t bfp(uint_xlen_t rs1, uint_xlen_t rs2)
{
    int len = (rs2 >> 24) & 15;
    int off = (rs2 >> 16) & (XLEN-1);
    len = len ? len : 16;
    uint_xlen_t mask = rol(slo(0, len), off);
    uint_xlen_t data = rol(rs2, off);
    return (data & mask) | (rs1 & ~mask);
}
```

The layout of the control word in rs2 is as follows. LEN=0 encodes for LEN=16.

Placing bits from a0 in a1, with results in t0:

```
addi t0, zero, {length[3:0], offset[7:0]}
pack t0, a0, t0
bfp t0, a1, t0
```

(On RV64 packw would be used as second instruction in that sequence.)

Placing up to 16 constant bits in any contiguous region:

```
lui t0, ...
addi t0, t0, ...
bfp t0, a1, t0
```

Note that either above sequence only modifies one register, which makes them fuse-able sequences.

## 2.5 Bit Extract/Deposit (bext, bdep)

```
RV32, RV64:
bext rd, rs1, rs2
bdep rd, rs1, rs2

RV64 only:
bextw rd, rs1, rs2
bdepw rd, rs1, rs2
```

This instructions implement the generic bit extract and bit deposit functions. This operation is also referred to as bit gather/scatter, bit pack/unpack, parallel extract/deposit, compress/expand, or right\_compress/right\_expand.

bext collects LSB justified bits to rd from rs1 using extract mask in rs2.

bdep writes LSB justified bits from rs1 to rd using deposit mask in rs2.

```
uint_xlen_t bext(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t r = 0;
    for (int i = 0, j = 0; i < XLEN; i++)
        if ((rs2 >> i) & 1) {
            if ((rs1 >> i) & 1)
                r |= uint_xlen_t(1) << j;
            j++;
        }
    return r;
}
uint_xlen_t bdep(uint_xlen_t rs1, uint_xlen_t rs2)
    uint_xlen_t r = 0;
    for (int i = 0, j = 0; i < XLEN; i++)
        if ((rs2 >> i) & 1) {
            if ((rs1 >> j) & 1)
                r |= uint_xlen_t(1) << i;
            j++;
        }
    return r;
}
```

Implementations may choose to use smaller multi-cycle implementations of bext and bdep, or even emulate the instructions in software.

Even though multi-cycle bext and bdep often are not fast enough to outperform algorithms that use sequences of shifts and bit masks, dedicated instructions for those operations can still be of great advantage in cases where the mask argument is not constant.

For example, the following code efficiently calculates the index of the tenth set bit in a0 using bdep:

```
li a1, 0x00000200
bdep a0, a1, a0
ctz a0, a0
```

For cases with a constant mask an optimizing compiler would decide when to use bext or bdep based on the optimization profile for the concrete processor it is optimizing for. This is similar to the decision whether to use MUL or DIV with a constant, or to perform the same operation using a longer sequence of much simpler operations.

The bext and bdep instructions are equivalent to the x86 BMI2 instructions PEXT and PDEP. But there is much older prior art. For example, the soviet BESM-6 mainframe computer, designed and built in the 1960s, had APX/AUX instructions with almost the same semantics. [1] (The BESM-6 APX/AUX instructions packed/unpacked at the MSB end instead of the LSB end. Otherwise it is the same instruction.)

Efficient hardware implementations of bext and bdep are described in [13] and demonstrated in [25].

### 2.6 Carry-Less Multiply (clmul, clmulh, clmulr)

```
RV32, RV64:
clmul rd, rs1, rs2
clmulh rd, rs1, rs2
clmulr rd, rs1, rs2
RV64 only:
clmulw rd, rs1, rs2
clmulw rd, rs1, rs2
clmulhw rd, rs1, rs2
clmulrw rd, rs1, rs2
```

Calculate the carry-less product [21] of the two arguments. clmul produces the lower half of the carry-less product and clmulh produces the upper half of the 2·XLEN carry-less product.

Carry-less multiplication is equivalent to multiplication in the polynomial ring over GF(2).

clmulr produces bits 2·XLEN-2:XLEN-1 of the 2·XLEN carry-less product. That means clmuln is equivalent to clmulr followed by a 1-bit right shift. (The MSB of a clmuln result is always zero.) Another equivalent definition of clmulr is clmulr(a,b) := rev(clmul(rev(a), rev(b))). (The "r" in clmulr means reversed.)

Unlike mulh[[s]u], we add a \*W variant of clmulh. This is because we expect some code to use 32-bit clmul intrisics, even on 64-bit architectures. For example in cases where data is processed in 32-bit chunks.

```
uint_xlen_t clmul(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t x = 0;
    for (int i = 0; i < XLEN; i++)
        if ((rs2 >> i) & 1)
            x ^= rs1 << i;
    return x;
}
uint_xlen_t clmulh(uint_xlen_t rs1, uint_xlen_t rs2)
    uint_xlen_t x = 0;
    for (int i = 1; i < XLEN; i++)
        if ((rs2 >> i) & 1)
            x = rs1 \gg (XLEN-i);
    return x;
}
uint_xlen_t clmulr(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t x = 0;
    for (int i = 0; i < XLEN; i++)
        if ((rs2 >> i) & 1)
            x = rs1 \gg (XLEN-i-1);
    return x;
}
```

The classic applications for clmul are Cyclic Redundancy Check (CRC) [11, 26] and Galois/Counter Mode (GCM), but more applications exist, including the following examples.

There are obvious applications in hashing and pseudo random number generations. For example, it has been reported that hashes based on carry-less multiplications can outperform Google's CityHash [17].

clmul of a number with itself inserts zeroes between each input bit. This can be useful for generating Morton code [23].

clmul of a number with -1 calculates the prefix XOR operation. This can be useful for decoding gray codes.

Another application of XOR prefix sums calculated with clmul is branchless tracking of quoted strings in high-performance parsers. [16]

Carry-less multiply can also be used to implement Erasure code efficiently. [14]

SPARC introduced similar instructions (XMULX, XMULXHI) in SPARC T3 in 2010. [6]

TI C6000 introduced a similar instruction (XORMPY) in C64x+. [7]

## 2.7 CRC Instructions (crc32.[bhwd], crc32c.[bhwd])

```
RV32, RV64:

crc32.b rd, rs

crc32.w rd, rs

crc32c.b rd, rs

crc32c.b rd, rs

crc32c.b rd, rs

crc32c.w rd, rs

crc32c.w rd, rs

crc32c.w rd, rs
```

Unary Cyclic Redundancy Check (CRC) instructions that interpret the bits of rs1 as a CRC32/CRC32C state and perform a polynomial reduction of that state shifted left by 8, 16, 32, or 64 bits.

The instructions return the new CRC32/CRC32C state.

The crc32.w/crc32c.w instructions are equivalent to executing crc32.h/crc32c.h twice, and crc32.h/crc32c.h instructions are equivalent to executing crc32.b/crc32c.b twice.

All 8 CRC instructions operate on bit-reflected data.

```
uint_xlen_t crc32(uint_xlen_t x, int nbits)
{
    for (int i = 0; i < nbits; i++)</pre>
        x = (x >> 1) ^ (0xEDB88320 & ^((x&1)-1));
    return x;
}
uint_xlen_t crc32c(uint_xlen_t x, int nbits)
{
    for (int i = 0; i < nbits; i++)</pre>
        x = (x >> 1) ^ (0x82F63B78 & ^ ((x&1)-1));
    return x;
}
uint_xlen_t crc32_b(uint_xlen_t rs1) { return crc32(rs1, 8); }
uint_xlen_t crc32_h(uint_xlen_t rs1) { return crc32(rs1, 16); }
uint_xlen_t crc32_w(uint_xlen_t rs1) { return crc32(rs1, 32); }
uint_xlen_t crc32c_b(uint_xlen_t rs1) { return crc32c(rs1, 8); }
uint_xlen_t crc32c_h(uint_xlen_t rs1) { return crc32c(rs1, 16); }
uint_xlen_t crc32c_w(uint_xlen_t rs1) { return crc32c(rs1, 32); }
```

```
#if XLEN > 32
uint_xlen_t crc32_d (uint_xlen_t rs1) { return crc32 (rs1, 64); }
uint_xlen_t crc32c_d(uint_xlen_t rs1) { return crc32c(rs1, 64); }
#endif
```

Payload data must be XOR'ed into the LSB end of the state before executing the CRC instruction. The following code demonstrates the use of crc32.b:

```
uint32_t crc32_demo(const uint8_t *p, int len)
{
   uint32_t x = 0xfffffffff;
   for (int i = 0; i < len; i++) {
      x = x ^ p[i];
      x = crc32_b(x);
   }
   return ~x;
}</pre>
```

In terms of binary polynomial arithmetic those instructions perform the operation

$$rd'(x) = (rs1'(x) \cdot x^N) \mod \{1, P'\}(x),$$

with  $N \in \{8, 16, 32, 64\}$ ,  $P = 0xEDB8_8320$  for CRC32 and  $P = 0x82F6_3B78$  for CRC32C, a' denoting the XLEN bit reversal of a, and  $\{a, b\}$  denoting bit concatenation. Note that for example for CRC32  $\{1, P'\} = 0x1_04C1_1DB7$  on RV32 and  $\{1, P'\} = 0x1_04C1_1DB7_0000_0000$  on RV64.

These dedicated CRC instructions are meant for RISC-V implementations without fast multiplier and therefore without fast clmul[h]. For implementations with fast clmul[h] it is recommended to use the methods described in [11] and demonstrated in [26] that can process XLEN input bits using just one carry-less multiply for arbitrary CRC polynomials.

In applications where those methods are not applicable it is possible to emulate the dedicated CRC instructions using two carry-less multiplies that implement a Barrett reduction. The following example implements a replacement for crc32.w (RV32).

```
crc32_w:
    li t0, 0xF7011641
    li t1, 0xEDB88320
    clmul a0, a0, t0
    clmulr a0, a0, t1
    ret
```

# 2.8 Bit-Matrix Instructions (bmatxor, bmator, bmatflip, RV64 only)

```
RISC-V Bitmanip ISA

RV64 only:
bmator rd, rs1, rs2
bmatxor rd, rs1, rs2
bmatflip rd, rs
```

These are 64-bit-only instruction that are not available on RV32. On RV128 they ignore the upper half of operands and sign extend the results.

This instructions interpret a 64-bit value as 8x8 binary matrix.

bmatxor performs a matrix-matrix multiply with boolean AND as multiply operator and boolean XOR as addition operator.

bmator performs a matrix-matrix multiply with boolean AND as multiply operator and boolean OR as addition operator.

bmatflip is a unary operator that transposes the source matrix. It is equivalent to zip; zip; zip on RV64.

```
uint64_t bmatflip(uint64_t rs1)
{
    uint64_t x = rs1;
    x = shf164(x, 31);
    x = shf164(x, 31);
    x = shf164(x, 31);
    return x;
}
uint64_t bmatxor(uint64_t rs1, uint64_t rs2)
    // transpose of rs2
    uint64_t rs2t = bmatflip(rs2);
    uint8_t u[8]; // rows of rs1
    uint8_t v[8]; // cols of rs2
    for (int i = 0; i < 8; i++) {
        u[i] = rs1 >> (i*8);
        v[i] = rs2t >> (i*8);
    }
    uint64_t x = 0;
    for (int i = 0; i < 64; i++) {
        if (pcnt(u[i / 8] & v[i % 8]) & 1)
            x |= 1LL << i;
    }
    return x;
}
```

```
uint64_t bmator(uint64_t rs1, uint64_t rs2)
{
    // transpose of rs2
    uint64_t rs2t = bmatflip(rs2);
    uint8_t u[8]; // rows of rs1
    uint8_t v[8]; // cols of rs2
    for (int i = 0; i < 8; i++) {
        u[i] = rs1 >> (i*8);
        v[i] = rs2t >> (i*8);
    }
    uint64_t x = 0;
    for (int i = 0; i < 64; i++) {
        if ((u[i / 8] & v[i % 8]) != 0)
            x = 1LL \ll i;
    }
    return x;
}
```

Among other things, bmatxor/bmator can be used to perform arbitrary permutations of bits within each byte (permutation matrix as 2nd operand) or perform arbitrary permutations of bytes within a 64-bit word (permutation matrix as 1st operand).

There are similar instructions in Cray XMT [5]. The Cray X1 architecture even has a full 64x64 bit matrix multiply unit [4]. (See Section 4.6 for how to implement 64x64 bit matrix operations with bmat[x]or.)

The MMIX architecture has MOR and MXOR instructions with the same semantic. [15, p. 182f]

The x86 EVEX/VEX/SSE instruction GF2P8AFFINEQB is equivalent to bmatxor.

The bmm.8 instruction proposed in [12] is also equivalent to bmatxor.

# 2.9 Ternary Bit-Manipulation Instructions

## 2.9.1 Conditional Mix (cmix)

```
RV32, RV64:
cmix rd, rs2, rs1, rs3
```

(Note that the assembler syntax of cmix has the rs2 argument first to make assembler code more readable. But the reference C code code below uses the "architecturally correct" argument order rs1, rs2, rs3.)

The cmix rd, rs2, rs1, rs3 instruction selects bits from rs1 and rs3 based on the bits in the control word rs2.

```
uint_xlen_t cmix(uint_xlen_t rs1, uint_xlen_t rs2, uint_xlen_t rs3)
{
    return (rs1 & rs2) | (rs3 & ~rs2);
}
```

It replaces sequences like the following.

```
and rd, rs1, rs2
andn t0, rs3, rs2
or rd, rd, t0
```

Using cmix a single butterfly stage can be implemented in only two instructions. Thus, arbitrary bit-permutations can be implemented using only 18 instruction (32 bit) or 22 instructions (64 bits).

### 2.9.2 Conditional Move (cmov)

```
RISC-V Bitmanip ISA RV32, RV64:
cmov rd, rs2, rs1, rs3
```

(Note that the assembler syntax of cmov has the rs2 argument first to make assembler code more readable. But the reference C code code below uses the "architecturally correct" argument order rs1, rs2, rs3.)

The cmov rd, rs2, rs1, rs3 instruction selects rs1 if the control word rs2 is non-zero, and rs3 if the control word is zero.

```
uint_xlen_t cmov(uint_xlen_t rs1, uint_xlen_t rs2, uint_xlen_t rs3)
{
    return rs2 ? rs1 : rs3;
}
```

The cmov instruction helps avoiding branches, which can lead to better performance, and helps with constant-time code as used in some cryptography applications.

### 2.9.3 Funnel Shift (fsl, fsr, fsri)

```
RV32, RV64:

fsl rd, rs1, rs3, rs2
fsr rd, rs1, rs3, imm

RV64 only:
fslw rd, rs1, rs3, rs2
fsrw rd, rs1, rs3, rs2
fsriw rd, rs1, rs3, rs2
fsriw rd, rs1, rs3, imm
```

(Note that the assembler syntax for funnel shifts has the rs2 argument last to make assembler code more readable. But the reference C code code below uses the "architecturally correct" argument order rs1, rs2, rs3.)

The fsl rd, rs1, rs2 instruction creates a  $2 \cdot \text{XLEN}$  word by concatenating rs1 and rs3 (with rs1 in the MSB half), rotate-left-shifts that word by the amount indicated in the  $log_2(\text{XLEN})$ + 1 LSB bits in rs2, and then writes the MSB half of the result to rd.

The fsr rd, rs1, rs2 instruction creates a  $2 \cdot \text{XLEN}$  word by concatenating rs1 and rs3 (with rs1 in the LSB half), rotate-right-shifts that word by the amount indicated in the  $log_2(\text{XLEN}) + 1$  LSB bits in rs2, and then writes the LSB half of the result to rd.

```
uint_xlen_t fsl(uint_xlen_t rs1, uint_xlen_t rs2, uint_xlen_t rs3)
    int shamt = rs2 & (2*XLEN - 1);
    uint_xlen_t A = rs1, B = rs3;
    if (shamt >= XLEN) {
        shamt -= XLEN;
        A = rs3;
        B = rs1;
    return shamt ? (A << shamt) | (B >> (XLEN-shamt)) : A;
}
uint_xlen_t fsr(uint_xlen_t rs1, uint_xlen_t rs2, uint_xlen_t rs3)
{
    int shamt = rs2 & (2*XLEN - 1);
    uint_xlen_t A = rs1, B = rs3;
    if (shamt >= XLEN) {
        shamt -= XLEN;
        A = rs3;
        B = rs1;
    }
    return shamt ? (A >> shamt) | (B << (XLEN-shamt)) : A;
}
```

A shift unit capable of either fsl or fsr is capable of performing all the other shift functions, including the other funnel shift, with only minimal additional logic.

For any values of A, B, and C:

```
fsl(A, B, C) = fsr(A, -B, C)
```

And for any values x and  $0 \le \text{shamt} < \text{XLEN}$ :

```
sll(x, shamt) == fsl(x, shamt, 0)
srl(x, shamt) == fsr(x, shamt, 0)
sra(x, shamt) == fsr(x, shamt, sext_x)
slo(x, shamt) == fsl(x, shamt, ~0)
sro(x, shamt) == fsr(x, shamt, ~0)
ror(x, shamt) == fsr(x, shamt, x)
rol(x, shamt) == fsl(x, shamt, x)
```

Furthermore an RV64 implementation of either fsl or fsr is capable of performing the \*W versions of all shift operations with only a few gates of additional control logic.

On RV128 there is no fsri instruction. But there is fsriw and fsrid.

## 2.10 Unsigned address calculation instructions

Consider C code that's using unsigned 32-bit ints as array indices. For example:

```
char addiwu_demo(char *p, unsigned int i) {
  return p[i-1];
}
int slliuw_demo(int *p, unsigned int i, unsigned int j) {
  return p[i^j];
}
```

In both cases the expression within p[...] must overflow according to 32-bit arithmetic, then be zero-extended, and then this zero-extended result must be used in the address calculation.

The instructions below make sure that no explicit zext.w instruction is needed in those cases, to make sure there is no systematic performance penalty for code like shown above on RV64 compared to RV32.

### 2.10.1 Add/sub with postfix zero-extend (addwu, subwu, addiwu)

```
RV64:
addwu rd, rs1, rs2
subwu rd, rs1, rs2
addiwu rd, rs1, imm
```

These instructions are identical to addw, subw, addiw, except that bits XLEN-1:32 of the result are cleared after the addition. I.e. these instructions zero-extend instead of sign-extend the 32-bit result

```
uint_xlen_t addwu(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t result = rs1 + rs2;
    return (uint32_t)result;
}
uint_xlen_t subwu(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t result = rs1 - rs2;
    return (uint32_t)result;
}
```

The 12-bit immediate to addiwn is sign-extended, exactly like the immediate to addiw.

### 2.10.2 Add/sub/shift with prefix zero-extend (addu.w, subu.w, slliu.w)

```
RISC-V Bitmanip ISA
addu.w rd, rs1, rs2
subu.w rd, rs1, rs2
slliu.w rd, rs1, imm
```

slliu.w is identical to slli, except that bits XLEN-1:32 of the rs1 argument are cleared before the shift.

addu.w and subu.w are identical to add and sub, except that bits XLEN-1:32 of the rs2 argument are cleared before the add/subtract.

```
uint_xlen_t slliuw(uint_xlen_t rs1, int imm)
{
    uint_xlen_t rs1u = (uint32_t)rs1;
    int shamt = imm & (XLEN - 1);
    return rs1u << shamt;
}
uint_xlen_t adduw(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t rs2u = (uint32_t)rs2;
    return rs1 + rs2u;
}
uint_xlen_t subuw(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t rs2u = (uint32_t)rs2;
    return rs1 - rs2u;
}</pre>
```

### 2.11 Opcode Encodings

This chapter contains proposed encodings for most of the instructions described in this document. **DO NOT IMPLEMENT THESE OPCODES YET.** We are trying to get official opcodes assigned and will update this chapter soon with the official opcodes.

The andn, orn, and xnor instruction are encoded the same way as and, or, and xor, but with op[30] set, mirroring the encoding scheme used for add and sub.

All shift instructions use funct3=001 for left shifts and funct3=101 for right shifts.

op[26]=1 selects funnel shifts. For funnel shifts op[30:29] is part if the 3rd operand and therefore unused for encoding the operation. For all other shift operations op[26]=0.

fsri is also encoded with op[26]=1, leaving a 6 bit immediate. The 7th bit, that is necessary to perform a 128 bit funnel shift on RV64, can be emulated by swapping rs1 and rs3.

There is no shfliw instruction. The slliu.w instruction occupies the encoding slot that would be occupied by shfliw.

On RV128 op [26] contains the MSB of the immediate for the shift instructions. Therefore there is no FSRI instruction on RV128. (But there is FSRIW/FSRID.)

		SLL	SRL	SRA		SLO	SRO		ROL	ROR		FSL	FSR
op[30]		0	0	1	-	0	0		1	1	1	-	_
op[29]		0	0	0		1	1		1	1		-	-
op[26]		0	0	0		0	0		0	0		1	1
funct3	3 I	001	101	101	1	001	101	1	001	101	Ι	001	101

Only an encoding for RORI exists, as ROLI can be implemented with RORI by negating the immediate. Unary functions are encoded in the spot that would correspond to ROLI, with the function encoded in the 5 LSB bits of the immediate.

The CRC instructions are encoded as unary instructions with op [24] set. The polynomial is selected via op [23], with op [23]=0 for CRC32 and op [23]=1 for CRC32C. The width is selected with op [22:20], using the same encoding as is used in funct3 for load/store operations.

cmix and cmov are encoded using the two remaining ternary operator encodings in funct3=001 and funct3=101. (There are two ternary operator encodings per minor opcode using the op[26]=1 scheme for marking ternary OPs.)

The single-bit instructions are also encoded within the shift opcodes, with op[27] set, and using op[30] and op[29] to select the operation:

	-	SBCLR	SBSET	SBINV		SBEXT	GORC	GREV
op[30]		1	0	1		1	0	1
op[29]		0	1	1		0	1	1
op[27]		1	1	1		1	1	1
funct3		001	001	001		101	101	101

There is no sbextiw instruction as it can be emulated trivially using sbexti. However, there is

sbsetiw, sbclriw, and sbinviw as changing bit 31 would change the sign extend. There are non-immediate \*W instructions of all single-bit instructions, including sbextw, because the number of used bits in rs2 is different in sbext and sbextw.

GORC and GREV are encoded in the two remaining slots in the single-bit instruction encoding space.

The remaining instructions are encoded within funct7=0000100 and funct7=0000101.

The funct7=0000101 block contains clmul[hr], min[u], and max[u].

The encoding of clmul, clmulr, clmulh is identical to the encoding of mulh, mulhsu, mulhu, except that op[27]=1.

The encoding of min[u]/max[u] uses funct3=100..111. The funct3 encoding matches op[31:29] of the AMO min/max functions.

The remaining instructions are encoded within funct7=0000100. The shift-like shf1/unshf1 instructions uses the same funct3 values as the shift operations. bdep and bext are encoded in a way so that funct3[2] selects the "direction", similar to shift operations.

bmat[x] or use funct3=011 and funct3=111 in funct7=0000100.

pack occupies funct3=100 in funct7=0000100.

addwu and subwu are encoded like addw and subw, except that op [25] = 1 and op [27] = 1.

addu.w and subu.w are encoded like addw and subw, except that op [27] =1.

addiwu is encoded using funct3=100 (XOR) instead of funct3=000 in OP-32.

Finally, RV64 has \*W instructions for all bitmanip instructions, with the following exceptions:

andn, cmix, cmov, min[u], max[u] have no \*W variants because they already behave in the way a \*W instruction would when presented with sign-exteded 32-bit arguments.

bmatflip, bmatxor, bmator have no \*W variants because they are 64-bit only instructions.

crc32. [bhwd], crc32c. [bhwd] have no \*W variants because crc32[c].w is deemed sufficient.

There is no [un]shfliw, as a perfect outer shuffle always preserves the MSB bit, thus [un]shfli preserves proper sign extension when the upper bit in the control word is set. There's still [un]shflw that masks that upper control bit and sign-extends the output.

Relevant instruction encodings from the base ISA are included in the table below and are marked with a \*.

|-----|

Pending changes for v0.92 of the RISC-V Bitmanip Spec (+ for addition, - for removal):

### 2.12 Future compressed instructions

The RISC-V ISA has no dedicated instructions for bitwise inverse (not). Instead not is implemented as xori rd, rs, -1 and neg is implemented as sub rd, x0, rs.

In bitmanipulation code not is a very common operation. But there is no compressed encoding for those operation because there is no c.xori instruction.

On RV64 (and RV128) zext.w and zext.d (pack and packw) are commonly used to zero-extend unsigned values <XLEN.

It presumably would make sense for a future revision of the "C" extension to include compressed opcodes for those instructions.

An encoding with the constraint rd = rs would fit nicely in the reserved space in c.addi16sp/c.lui.

$ \begin{array}{c ccccccccccccccccccccccccccccccccccc$	15 14 13	12	11 10	9	8 7	6 5	4	3 2	1 0	
$ \begin{array}{c ccccccccccccccccccccccccccccccccccc$	011	nzimm[9]		2			nzimm[4 6 8:7 5]			C.ADDI16SP $(RES, nzimm=\theta)$
011 0 01 $rs1'/rd'$ 0 01 $C.ZEXT.W$ (RV64/128)	011	nzimm[17]	$\mathrm{rd}_{7}$	$rd \neq \{0, 2\}$			nm[16]	6:12]	01	C.LUI (RES, nzimm=0; HINT, $rd=0$ )
· · · · · · · · · · · · · · · · · · ·	011	0	00	rs1	'/rd'		0		01	C.NOT
011 0 11 $rs1'/rd'$ 0 01 C.ZEXT.D (RV128)	011	0	01	rs1	$^{\prime}/\mathrm{rd}^{\prime}$		0		01	C.ZEXT.W (RV64/128)
	011	0	11	rs1	$^{\prime}/\mathrm{rd}^{\prime}$		0		01	C.ZEXT.D (RV128)

The entire RVC encoding space is 15.585 bits wide, the remaining reserved encoding space in RVC is 11.155 bits wide, not including space that is only reserved on RV32/RV64. This means that above encoding would use 0.0065% of the RVC encoding space, or 1.4% of the remaining reserved

RVC encoding space. Preliminary experiments have shown that NOT instructions alone make up approximately 1% of bitmanipulation code size. [27]

# 2.13 Micro architectural considerations and macro-op fusion for bit-manipulation

### 2.13.1 Fast MUL, MULH, MULHSU, MULHU

A lot of bit manipulation code depends on "multiply with magic number"-tricks. Often those tricks need the upper half of the 2·XLEN product. Therefore decent performance for the MUL and especially MULH[[S]U] instructions is important for fast bit manipulation code.

### 2.13.2 Fused load-immediate sequences

Bit manipulation code, even more than other code, requires a lot of "magic numbers", bitmasks, and other (usually large) constants. On some microarchitectures those can easily be loaded from a nearby data section using load instructions. On other microarchitectures however this comes at a high cost, and it is more efficient to load immediates using a sequence of instructions.

Loading a 32-bit constant:

```
lui rd, imm
addi rd, rd, imm
```

On RV64 a 64 bit constant can be loaded by loading two 32-bit constants and combining them with a PACK instruction:

```
lui tmp, imm
addi tmp, tmp, imm
lui rd, imm
addi rd, rd, imm
pack rd, rd, tmp
```

(Without the temporary register and without the PACK instruction more complex/diverse sequences are used to load 64-bit immediates. But the PACK instruction streamlines the pattern and thus simplifies macro-op fusion.)

A 32-bit core should be capable of fusing the lui+addi pattern.

In addition to that, a 64 bit core may consider fusing the following sequences as well:

```
lui rd, imm
addi rd, rd, imm
pack rd, rd, rs2
lui rd, imm
pack rd, rd, rs2
addi rd, zero, imm
pack rd, rd, rs2
```

Furthermore, a core may consider fusing 32-bit immediate loads with any ALU instruction, not just pack:

```
lui rd, imm
addi rd, rd, imm
alu_op rd, rd, rs2
lui rd, imm
alu_op rd, rd, rs2
addi rd, zero, imm
alu_op rd, rd, rs2
```

And finally, a 64-bit core should fuse sequences with addiwn as well as addi, for loading unsigned 32-bit numbers that have their MSB set. This is often the case with masks in bit manipulation code.

### 2.13.3 Fused \*-bfp sequences

The bfp instruction is most commonly used in one of the following sequences:

```
addi rd, zero, ...
pack rd, rs2, rd
bfp rd, rs1, rd
lui rd, ...
addi rd, rd, ...
bfp rd, rs1, rd
```

Either sequence only reads at most two registers and only writes one register, making them ideal candidates for macro-op fusion.

### 2.13.4 Fused \*-not sequences

Preliminary experiments have shown that NOT instructions make up approximately 1% of bitmanipulation code size, more when looking at dynamic instruction count. [27]

Therefore it makes sense to fuse NOT instructions with other ALU instructions, if possible.

The most important form of NOT fusion is postfix fusion:

```
alu_op rd, rs1, rs2
not rd, rd
```

A future compressed NOT instruction would help keeping those fused sequences short.

### 2.13.5 Fused pack-permute sequences

A pack[hu] instruction is often followed by a destructive permutation or shift instruction with immediate ([un]shfli, rori, slli, etc).

This makes it attractive to place the few MUXes for pack[hu] instructions infront of the shift unit, so that such sequences can be fused.

### 2.13.6 Fused \*-srli and \*-srai sequences

Pairs of left and right shifts are common operations for extracting a bit field.

To extract the contiguous bit field starting at pos with length len from rs (with pos > 0, len > 0, and pos + len  $\le$  XLEN):

```
slli rd, rs, (XLEN-len-pos)
srli rd, rd, (XLEN-len)
```

Using srai instead of srli will sign-extend the extracted bit-field.

Similarly, placing a bit field with length len at the position pos:

```
slli rd, rs, (XLEN-len)
srli rd, rd, (XLEN-len-pos)
```

If possible, an implementation should fuse the following macro ops:

```
alu_op rd, rs1, rs2
srli rd, rd, imm
alu_op rd, rs1, rs2
srai rd, rd, imm
```

Note that the postfix right shift instruction can use a compressed encoding, yielding a 48-bit fused instruction if alu\_op is a 32-bit instruction.

For generating masks, i.e. constants with one continuous run of 1 bits, a sequence like the following can be used that would utilize postfix fusion of right shifts:

```
sroi rd, zero, len
c.srli rd, (XLEN-len-pos)
```

This can be a useful sequence on RV64, where loading an arbitrary 64-bit constant would usually require at least 96 bits (using c.ld).

### 2.13.7 Fused sequences for logic operations

RISC-V has dedicated instructions for branching on equal/not-equal. But C code such as the following would require set-equal and set-not-equal instructions, similar to slt.

```
int is_equal = (a == b);
int is_noteq = (c != d);
```

Those can be implemented using the following fuse-able sequences:

```
sub rd, rs1, rs2
sltui rd, rd, 1

sub rd, rs1, rs2
sltu rd, zero, rd

Likewise for logic OR:
  int logic_or = (c || d);
  or rd, rs1, rs2
  sltu rd, zero, rd

And for logic AND, if rd != rs2:
  int logic_and = (c && d);
  orc rd, rs1
  and rd, rd, rs2
  sltu rd, zero, rd
```

### 2.13.8 Fused ternary ALU sequences

Architectures with support for ternary operations may want to support fusing two ALU operations.

```
alu_op rd, ...
alu_op rd, rd, ...
```

This would be a postfix-fusion pattern, extending the postfix shift-right fusion described in Section 2.13.6.

Candidates for this kind of postfix fusion would be simple ALU operations, specifically AND/OR/X-OR/ADD/SUB and ANDI/ORI/XORI/ADDI/SUBI.

### 2.13.9 Pseudo-ops for fused sequences

Assembler pseudo-ops for not postfix fusion:

```
nand rd, rs1, rs2 -> and rd, rs1, rs2; not rd, rd nor rd, rs1, rs2 -> or rd, rs1, rs2; not rd, rd
```

Assembler bitfield pseudo-ops for sr[la]i postfix fusion:

```
bfext rd, rs, len, pos -> slli rd, rs, (XLEN-len-pos); srai rd, rd, (XLEN-len)
bfextu rd, rs, len, pos -> slli rd, rs, (XLEN-len-pos); srli rd, rd, (XLEN-len)
bfmak rd, len, pos -> sroi rd, zero, len; srli rd, rd, (XLEN-len-pos)
```

The names bfext, bfextu, and bfmak are borrowed from m88k, that had dedicated instructions of those names (without bf-prefix) with equivalent semantics. [3, p. 3-28]

Sign-extending bytes and half-words are special cases of bfext:

```
sext.b rd, rs -> slli rd, rs, (XLEN-8); srai rd, rd, (XLEN-8)
sext.h rd, rs -> slli rd, rs, (XLEN-16); srai rd, rd, (XLEN-16)
```

### 2.14 C intrinsics via <rvintrin.h>

A C header file <rvintrin.h> is provided that contains assembler templates for directly creating assembler instructions from C code.

The header defines \_rv\_\*(...) functions that operate on the long data type, \_rv32\_\*(...) functions that operate on the int32\_t data type, and \_rv64\_\*(...) functions that operate on the int64\_t data type. The \_rv64\_\*(...) functions are only available on RV64. See table 2.9 for a complete list of intrinsics defined in <ruintrin.h>.

Usage example:

```
#include <rvintrin.h>
int find_nth_set_bit(unsigned int value, int cnt) {
  return _rv32_ctz(_rv32_bdep(1 << cnt, value));
}</pre>
```

Defining RVINTRIN\_EMULATE before including <rvintrin.h> will define plain C functions that emulate the behavior of the RISC-V instructions. This is useful for testing software on non-RISC-V platforms.

# Chapter 3

# Reference Implementations

### 3.1 Verilog reference implementations

We have implemented Verilog cores for all instructions proposed in this specification. These cores are permissively licensed under the ISC license and can be obtained from https://github.com/riscv/riscv-bitmanip/tree/master/verilog.

For evaluation purposes we synthesized these cores for RV32 and RV64 to the following mockup ASIC cell library:

Cell	Gate Count	Cell	Gate Count
NOT	0.5	AOI3	1.5
NAND	1	OAI3	1.5
NOR	1	AOI4	2
XOR	3	OAI4	2
XNOR	3	NMUX	2.5
DFF	4	MUX	3

For comparison we also synthesized the rocket-chip MulDiv cores obtained using the following rocket-chip configurations:

```
class MulDivConfig64 extends Config(
   new WithFastMulDiv ++
   new DefaultConfig
)

class MulDivConfig32 extends Config(
   new WithRV32 ++
   new WithFastMulDiv ++
   new DefaultConfig
)
```

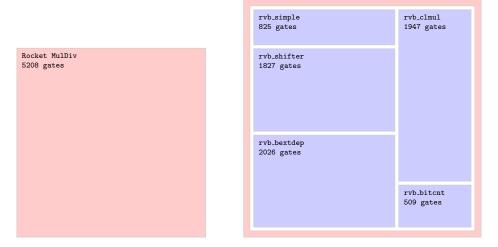

Figure 3.1: Area of 32-bit Rocket MulDiv core (left) compared to a complete implementation of all 32-bit instructions proposed in this specification except CRC instructions (right).

The following table lists the verilog reference cores and the instructions they implement:

Module	Instructions
rvb_bextdep	bext bdep grev gorc shfl unshfl
$rvb\_clmul$	clmul clmulr clmulh
${\tt rvb\_shifter}$	sll srl sra slo sro rol ror fsl fsr slliu.w
	sbset sbclr sbinv sbext bfp
$rvb\_bmatxor$	bmatxor bmator
$rvb\_simple$	min max minu maxu andn orn
	xnor pack cmix cmov addiwu addwu
	subwu adduw subuw
${\tt rvb\_bitcnt}$	clz ctz pcnt bmatflip
$rvb\_full$	All of the above

On RV64 these cores also implement all \*W instruction variants of the above instructions.

Note that rvb\_shifter also implements the base ISA sll, srl, and sra instructions. Thus it can replace an existing implementation of the base ISA shift instructions.

Fig. 3.1 shows the area comparison for RV32 and fig. 3.2 shows the comparison for RV64. The area of the red frame surrounding the blue rvb\_\* modules accurately represents the added area by the rvb\_full wrapper module.

Regarding timing we evaluate the longest paths for rvb\_full and rocket-chip MulDiv, measured in gate delays:

	RV32	RV64
rvb_full	30	57
MulDiv	43	68

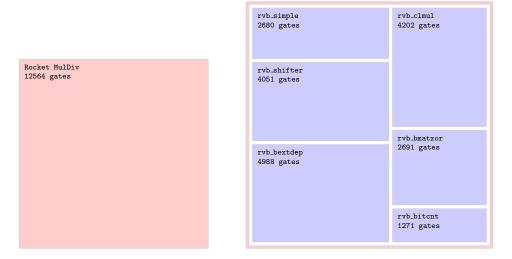

Figure 3.2: Area of 64-bit Rocket MulDiv core (left) compared to a complete implementation of all 64-bit instructions proposed in this specification except CRC instructions (right).

All rvb\_\* reference cores provide single-cycle implementations of their functions, with the exception of rvb\_clmul which requires 4 cycles for a 32-bit carry-less multiply and 8 cycles for a 64-bit carry-less multiply.

# 3.2 Fast C reference implementations

GCC has intrinsics for the bit counting instructions clz, ctz, and pcnt. So a performance-sensitive application (such as an emulator) should probably just use those:

```
uint32_t fast_clz32(uint32_t rs1)
{
    if (rs1 == 0)
        return 32;
    assert(sizeof(int) == 4);
    return __builtin_clz(rs1);
}
uint64_t fast_clz64(uint64_t rs1)
{
    if (rs1 == 0)
        return 64;
    assert(sizeof(long long) == 8);
    return __builtin_clzll(rs1);
}
```

```
uint32_t fast_ctz32(uint32_t rs1)
  {
      if (rs1 == 0)
          return 32;
      assert(sizeof(int) == 4);
      return __builtin_ctz(rs1);
  }
 uint64_t fast_ctz64(uint64_t rs1)
  {
      if (rs1 == 0)
          return 64;
      assert(sizeof(long long) == 8);
      return __builtin_ctzll(rs1);
  }
 uint32_t fast_pcnt32(uint32_t rs1)
      assert(sizeof(int) == 4);
      return __builtin_popcount(rs1);
  }
 uint64_t fast_pcnt64(uint64_t rs1)
      assert(sizeof(long long) == 8);
      return __builtin_popcountll(rs1);
  }
For processors with BMI2 support GCC has intrinsics for bit extract and bit deposit instructions
(compile with -mbmi2 and include <x86intrin.h>):
 uint32_t fast_bext32(uint32_t rs1, uint32_t rs2)
  {
      return _pext_u32(rs1, rs2);
  }
 uint64_t fast_bext64(uint64_t rs1, uint64_t rs2)
  {
      return _pext_u64(rs1, rs2);
  }
 uint32_t fast_bdep32(uint32_t rs1, uint32_t rs2)
  {
      return _pdep_u32(rs1, rs2);
  }
 uint64_t fast_bdep64(uint64_t rs1, uint64_t rs2)
  {
      return _pdep_u64(rs1, rs2);
  }
```

For other processors we need to provide our own implementations. The following implementation

is a good compromise between code complexity and runtime:

```
uint_xlen_t fast_bext(uint_xlen_t rs1, uint_xlen_t rs2)
{
    uint_xlen_t c = 0, i = 0, mask = rs2;
    while (mask) {
        uint_xlen_t b = mask & ~((mask | (mask-1)) + 1);
        c |= (rs1 & b) >> (fast_ctz(b) - i);
        i += fast_pcnt(b);
        mask -= b;
    }
    return c;
}
uint_xlen_t fast_bdep(uint_xlen_t rs1, uint_xlen_t rs2)
    uint_xlen_t c = 0, i = 0, mask = rs2;
    while (mask) {
        uint_xlen_t b = mask & ~((mask | (mask-1)) + 1);
        c |= (rs1 << (fast_ctz(b) - i)) & b;</pre>
        i += fast_pcnt(b);
        mask -= b;
    }
    return c;
}
```

For the other Bitmanip instructions the C reference functions given in Chapter 2 are already reasonably efficient.

# Chapter 4

# **Example Applications**

This chapter contains a collection of short code snippets and algorithms using the Bitmanip extension. It also contains some examples of bit manipulation code that doesn't require any extension beyond the base ISA.

# 4.1 Basic Bitmanipulation

### 4.1.1 Bitfield extract

Extracting a bit field of length len at position pos can be done using two shift operations.

```
slli a0, a0, (XLEN-len-pos)
srli a0, a0, (XLEN-len)
```

Or using srai for a signed bit-field.

```
slli a0, a0, (XLEN-len-pos)
srai a0, a0, (XLEN-len)
```

### 4.1.2 Parity check

The parity of a word (xor of all bits) is the LSB of the population count.

```
pcnt a0, a0 andi a0, a0, 1
```

### 4.1.3 Rotate shift of bytes and half-words

Rotate right shift of the byte in a0 by the shift amount in a1, assuming a0 is stored in zero-extended form:

```
orc8 a0, a0
ror a0, a1
andi a0, a0, 255
```

And rotate right shift of the 16-bit half-word in a0 by the shift amount in a1, assuming a0 is stored in zero-extended form:

```
orc16 a0, a0
ror a0, a1
pack[w] a0, a0, zero
```

### 4.1.4 Rank and select

Rank and select are fundamental operations in succinct data structures [19].

select(a0, a1) returns the position of the a1th set bit in a0. It can be implemented efficiently using bdep and ctz:

```
select:
  sbset a1, zero, a1
  bdep a0, a1, a0
  ctz a0, a0
  ret
```

rank(a0, a1) returns the number of set bits in a0 up to and including position a1.

```
rank:
  not a1, a1
  sll a0, a1
  pcnt a0, a0
  ret
```

### 4.1.5 OR/AND/XOR-reduce in byte vectors

OR-ing the bytes in a register and returning the resulting byte is easy with GORC:

```
gorci a0, a0, -8
andi a0, 255
```

AND-ing can accomplished by applying De Morgan's laws:

```
not a0, a0
gorci a0, a0, -8
not a0, a0
andi a0, 255
```

XOR-ing can be accomplished with CLMUL (see also section 4.7).

```
andi a1, zero, 0x80 gorci a1, a1, -8 clmulr a0, a0, a1 andi a0, 255
```

Where the first two instructions (andi+gorci) just create the constant 0x8080..8080.

Finally, on RV64, XOR-ing the bytes in a register can also be accomplished with BMATXOR:

```
andi a1, zero, 0xff
bmatxor a0, a1, a0
```

### 4.1.6 Counting trailing non-zero bytes

Counting the trailing (LSB-end) non-zero bytes in a word is a helpful operation in optimized implementations of strlen() and strcpy():

```
int count_trailing_nonzero_bytes(long x)
{
  return _rv_ctz(~_rv_orc_b(x)) >> 3;
}
```

### 4.1.7 Finding bytes of certain values

Finding zero bytes is a useful operations for strchr() and memchr():

```
bool check_zero_bytes(long x)
{
  return ~_rv_orc_b(x) != 0;
}
```

To find other bytes we simply XOR the value with a mask of the byte value we are looking for:

```
bool check_byte(long x, unsigned char c)
{
  return ~_rv_orc_b(x ^ _rv_orc8(c)) != 0;
}
```

These schemes can easily be extended with ctz and pcnt to perform operations such as counting the number of bytes of a certain value within a word, or finding the position of the first such byte.

### 4.1.8 Fill right of most significant set bit

The "fill right" or "fold right" operation is a pattern commonly used in bit manipulation code. [8]

The straight-forward RV64 implementation requires 12 instructions:

With clz it can be implemented in only 4 instructions. Notice the handling of the case where x=0 using sltiu+addi.

Alternatively, a Trailing Bit Manipulation (TBM) code pattern can be used together with rev to implement this function in 4 instructions:

Finally, there is another implementation in 4 instructions using BMATOR, if we do not count the extra instructions for loading utility matrices.

```
uint64_t rfill_bmat(uint64_t x)
  uint64_t m0, m1, m2, t;
  m0 = 0xFF7F3F1F0F070301LL; // LD
  m1 = bmatflip(m0 << 8);</pre>
                             // SLLI, BMATFLIP
  m2 = -1LL;
                               // ADDI
  t = bmator(x, m0);
                               // BMATOR
  x = bmator(x, m2);
                              // BMATOR
  x = bmator(m1, x);
                              // BMATOR
                               // OR
  x \mid = t;
  return x;
}
```

### 4.1.9 Round to next power of two

One common application of rfill() is rounding up to the next power of two:

```
uint64_t round_pow2(uint64_t x)
{
  return rfill(x-1)+1;
}
```

This can also be implemented in just 4 instructions, if we don't care about the case where the above code overflows because x is already larger than the largest power-of-two representable in an uint64\_t.

Note that this code handles  $0 \to 0$  and  $1 \to 1$  correctly, i.e. equivialent to rfill(x-1)+1.

### 4.2 Packed vectors

### 4.2.1 Packing bytes

The following RV32 code packs the lower 8 bits from a0, a1, a2, a3 into a 32-bit word returned in a0, ignoring other bits in the input values.

```
packh a0, a0, a1
packh a1, a2, a3
pack a0, a0, a1
```

And the following RV64 code packs 8 bytes into a register.

```
packh a0, a0, a1
packh a1, a2, a3
packh a2, a4, a5
packh a3, a6, a7
packw a0, a0, a1
packw a1, a2, a3
pack a0, a0, a1
```

### 4.2.2 Permuting bytes

There are 24 ways of arranging the four bytes in a 32-bit word. ror, grev, and [un]shfl can perform any of those permutations in at most 3 instructions. Table 4.1 lists those sequences. [24]

Bytes	Instructions
ABCD	initial byte order
A B D C	ROR(24),SHFL(8),ROR(8)
A C B D	SHFL(8)
A C D B	ROR(8),GREV(8),SHFL(8)
ADBC	ROR(16),SHFL(8),ROR(24)
A D C B	ROR(8),GREV(8)
BACD	ROR(8),SHFL(8),ROR(24)
B A D C	GREV(8)
B C A D	ROR(16),SHFL(8),ROR(8)
B C D A	ROR(24)
BDAC	GREV(8),SHFL(8)
BDCA	ROR(24),SHFL(8)
CABD	ROR(8),GREV(24),SHFL(8)
C A D B	ROR(16),SHFL(8)
C B A D	ROR(8),GREV(24)
C B D A	SHFL(8),ROR(24)
CDAB	ROR(16)
CDBA	ROR(8),SHFL(8),ROR(8)
DABC	ROR(8)
DACB	SHFL(8),ROR(8)
DBAC	ROR(8),SHFL(8)
DBCA	GREV(24),SHFL(8)
D C A B	ROR(24),SHFL(8),ROR(24)
D C B A	GREV(24)

Table 4.1: Instruction sequences for arbitrary permutations of bytes in a 32-bit word.

### 4.2.3 Widening and narrowing

The [un]zip instructions can help with widening and narrowing packed vectors. For example, narrowing the bytes in two words into a single word with the values in nibbles with values from a0 in LSB half and values from a1 in MSB half:

```
unzip4 a0, a0
unzip4 a1, a1
pack a0, a0, a1
```

And widening the nibbles from a0 into bytes in a1 (MSB half) and a0 (LSB half), with zero extension:

```
srli a1, a0, XLEN/2
pack a0, a0, zero
zip4 a1, a1
zip4 a0, a0
```

And finally the same widening operation with sign extension:

```
addi t0, zero, 8 orc4 t0, t0 and t0, t0, a0 orc.n t0, t0 srli t1, t0, XLEN/2 srli a1, a0, XLEN/2 pack a1, a1, t1 pack a0, a0, t0 zip4 a1, a1 zip4 a0, a0
```

### 4.2.4 Shifting packed vector elements

Using zip we can re-arrange the bits in a packed vector of N elements so that a shift by k of each byte becomes a shift of Nk of the entire new vector. So we zip, shift, and then unzip to shuffle everything back. The number of zip and unzip is  $\log 2(N)$ . This works for all kinds of shift operations. For example, rotating a vector of bytes on RV32 in 6 instructions:

```
zip a0, a0
zip a0, a0
slli a1, a1, 2
ror a0, a0, a1
unzip a0, a0
unzip a0, a0
```

Because zip; zip; zip is equal to unzip; unzip on RV32, and equal to unzip; unzip on RV64, we need never more than 2 [un]zip on RV32, or 3 [un]zip on RV64.

### 4.2.5 Adding packed vectors

The following six instructions will add the elements of the two vectors passed in a0 and a1, and return the vector of sums in a0.

This expects a mask in a2 that marks the MSB bit of each vector element. For a vector of bytes this mask would be 0x8080...80 (which can be obtained in two instructions via orc8(0x80)).

```
xor a3, a0, a1
and a3, a3, a2
andn a0, a0, a2
andn a1, a1, a2
add a0, a0, a1
xor a0, a0, a3
```

### 4.3 Funnel shifts

A funnel shift takes two XLEN registers, concatenates them to a  $2 \times XLEN$  word, shifts that by a certain amount, then returns the lower half of the result for a right shift and the upper half of the result for a left shift.

The fsl, fsr, and fsri instructions perform funnel shifts.

### 4.3.1 Bigint shift

A common application for funnel shifts is shift operations in bigint libraries.

For example, the following functions implement rotate-shift operations for bigints made from n XLEN words.

```
void bigint_rol(uint_xlen_t data[], int n, int shamt)
  if (n <= 0)
    return;
  uint_xlen_t buffer = data[n-1];
  for (int i = n-1; i > 0; i--)
    data[i] = fsl(data[i], shamt, data[i-1]);
  data[0] = fsl(data[0], shamt, buffer);
}
void bigint_ror(uint_xlen_t data[], int n, int shamt)
  if (n <= 0)
    return;
  uint_xlen_t buffer = data[0];
  for (int i = 0; i < n-1; i++)
    data[i] = fsr(data[i], shamt, data[i+1]);
  data[n-1] = fsr(data[n-1], shamt, buffer);
}
```

These version only works for shift-amounts <XLEN. But functions supporting other kinds of shift operations, or shifts  $\geq$ XLEN can easily be built with fsl and fsr.

### 4.3.2 Parsing bit-streams

The following function parses n 27-bit words from a packed array of XLEN words:

```
void parse_27bit(uint_xlen_t *idata, uint_xlen_t *odata, int n)
  uint_xlen_t lower = 0, upper = 0;
  int reserve = 0;
  while (n--) {
    if (reserve < 27) {
      uint_xlen_t buf = *(idata++);
      lower |= sll(buf, reserve);
      upper = reserve ? srl(buf, -reserve) : 0;
      reserve += XLEN;
    }
    *(odata++) = lower & ((1 << 27)-1);
    lower = fsr(lower, 27, upper);
    upper = srl(upper, 27);
    reserve -= 27;
  }
}
```

And here the same thing in RISC-V assembler:

```
parse_27bit:
  li t1, 0
                         ; lower
  li t2, 0
                         ; upper
  li t3, 0
                         ; reserve
  li t4, 27
                         ; shamt
  slo t5, zero, t4
                         ; mask
                         ; while (n--)
  beqz a2, endloop
loop:
  addi a2, a2, -1
  bge t3, t4, output
                            ; if (reserve < 27)
  lw t6, 0(a0)
                                ; buf = *(idata++)
  addi a0, a0, 4
  sll t7, t6, t3
                                ; lower |= sll(buf, reserve)
  or t1, t1, t7
  sub t7, zero, t3
                                ; upper = reserve ? srl(buf, -reserve) : 0
  srl t7, t6, t7
  cmov t2, t3, t7, zero
  addi t3, t3, 32
                                ; reserve += XLEN;
output:
  and t6, t1, t5
                            ; *(odata++) = lower & ((1 << 27)-1)
  sw t6, 0(a1)
  addi a1, a1, 4
  fsr t1, t1, t2, t4
                            ; lower = fsr(lower, 27, upper)
  srl t2, t2, t4
                            ; upper = srl(upper, 27)
  sub t3, t3, t4
                            ; reserve -= 27
  bnez a2, loop
                         ; while (n--)
endloop:
```

A loop iteration without fetch is 9 instructions long, and a loop iteration with fetch is 17 instructions long.

Without ternary operators that would be 13 instructions and 22 instructions, i.e. assuming one cycle per instruction, that function would be about 30% slower without ternary instructions.

### 4.3.3 Fixed-point multiply

A fixed-point multiply is simply an integer multiply, followed by a right shift. If the entire dynamic range of XLEN bits should be useable for the factors, then the product before shift must be 2\*XLEN wide. Therefore mul+mulh is needed for the multiplication, and funnel shift instructions can help with the final right shift. For fixed-point numbers with N fraction bits:

```
mul_fracN:
  mulh a2, a0, a1
  mul a0, a0, a1
  fsri a0, a0, a2, N
  ret
```

## 4.4 Arbitrary bit permutations

This section lists code snippets for computing arbitrary bit permutations that are defined by data (as opposed to bit permutations that are known at compile time and can likely be compiled into shift-and-mask operations and/or a few instances of bext/bdep).

#### 4.4.1 Using butterfly operations

The following macro performs a stage-N butterfly operation on the word in a0 using the mask in a1.

```
grevi a2, a0, (1 << N) cmix a0, a1, a2, a0
```

The bitmask in a1 must be preformatted correctly for the selected butterfly stage. A butterfly operation only has a XLEN/2 wide control word. The following macros format the mask assuming those XLEN/2 bits in the lower half of a1 on entry:

```
bfly_msk_0:
   pack a1, a1, a1
   zip a1, a1

bfly_msk_1:
   pack a1, a1, a1
   zip2 a1, a1

bfly_msk_2:
   pack a1, a1, a1
   zip4 a1, a1
```

A sequence of  $2 \cdot log_2(XLEN) - 1$  butterfly operations can perform any arbitrary bit permutation (Beneš network):

```
butterfly(LOG2_XLEN-1)
butterfly(LOG2_XLEN-2)
...
butterfly(0)
...
butterfly(LOG2_XLEN-2)
butterfly(LOG2_XLEN-1)
```

Many permutations arising from real-world applications can be implemented using shorter sequences. For example, any sheep-and-goats operation (SAG, see section 4.4.4) with either the sheep or the goats bit reversed can be implemented in  $log_2(XLEN)$  butterfly operations.

Reversing a permutation implemented using butterfly operations is as simple as reversing the order of butterfly operations.

#### 4.4.2 Using omega-flip networks

The omega operation is a stage-0 butterfly preceded by a zip operation:

```
zip a0, a0
grevi a2, a0, 1
cmix a0, a1, a2, a0
```

The flip operation is a stage-0 butterfly followed by an unzip operation:

```
grevi a2, a0, 1 cmix a0, a1, a2, a0 unzip a0, a0
```

A sequence of  $log_2(XLEN)$  omega operations followed by  $log_2(XLEN)$  flip operations can implement any arbitrary 32 bit permutation.

As for butterfly networks, permutations arising from real-world applications can often be implemented using a shorter sequence.

#### 4.4.3 Using baseline networks

Another way of implementing arbitrary 32 bit permutations is using a baseline network followed by an inverse baseline network.

A baseline network is a sequence of  $log_2(XLEN)$  butterfly(0) operations interleaved with unzip operations. For example, a 32-bit baseline network:

```
butterfly(0)
unzip
butterfly(0)
unzip.h
butterfly(0)
unzip.b
butterfly(0)
unzip.n
butterfly(0)
```

An inverse baseline network is a sequence of  $log_2(XLEN)$  butterfly(0) operations interleaved with zip operations. The order is opposite to the order in a baseline network. For example, a 32-bit inverse baseline network:

```
butterfly(0)
zip.n
butterfly(0)
zip.b
butterfly(0)
zip.h
butterfly(0)
zip
```

A baseline network followed by an inverse baseline network can implement any arbitrary bit permutation.

#### 4.4.4 Using sheep-and-goats

The Sheep-and-goats (SAG) operation is a common operation for bit permutations. It moves all the bits selected by a mask (goats) to the LSB end of the word and all the remaining bits (sheep) to the MSB end of the word, without changing the order of sheep or goats.

The SAG operation can easily be performed using bext (data in a0 and mask in a1):

```
bext a2, a0, a1
not a1, a1
bext a0, a0, a1
pcnt a1, a1
ror a0, a0, a1
or a0, a0, a2
```

Any arbitrary bit permutation can be implemented in  $log_2(XLEN)$  SAG operations.

The Hacker's Delight describes an optimized standard C implementation of the SAG operation. Their algorithm takes 254 instructions (for 32 bit) or 340 instructions (for 64 bit) on their reference RISC instruction set. [9, p. 152f, 162f]

#### 4.4.5 Using bit-matrix multiply

bat[x]or performs a permutation of bits within each byte when used with a permutation matrix in rs2, and performs a permutation of bytes when used with a permutation matrix in rs1.

## 4.5 Mirroring and rotating bitboards

Bitboards are 64-bit bitmasks that are used to represent part of the game state in chess engines (and other board game AIs). The bits in the bitmask correspond to squares on a  $8 \times 8$  chess board:

```
56 57 58 59 60 61 62 63 48 49 50 51 52 53 54 55 40 41 42 43 44 45 46 47 32 33 34 35 36 37 38 39 24 25 26 27 28 29 30 31 16 17 18 19 20 21 22 23 8 9 10 11 12 13 14 15 0 1 2 3 4 5 6 7
```

Many bitboard operations are simple straight-forward operations such as bitwise-AND, but mirroring and rotating bitboards can take up to 20 instructions on x86.

#### 4.5.1 Mirroring bitboards

Flipping horizontally or vertically can easily done with grevi:

```
Flip horizontal:
63 62 61 60 59 58 57 56
                           RISC-V Bitmanip:
55 54 53 52 51 50 49 48
                              rev.b
 47 46 45 44 43 42 41 40
39 38 37 36 35 34 33 32
 31 30 29 28 27 26 25 24
                           x86:
 23 22 21 20 19 18 17 16
                              13 operations
 15 14 13 12 11 10 9
    6 5 4 3 2
Flip vertical:
 0 1 2 3 4 5 6 7
                           RISC-V Bitmanip:
 8 9 10 11 12 13 14 15
                              rev8
 16 17 18 19 20 21 22 23
 24 25 26 27 28 29 30 31
32 33 34 35 36 37 38 39
                           x86:
40 41 42 43 44 45 46 47
                              bswap
48 49 50 51 52 53 54 55
56 57 58 59 60 61 62 63
```

Rotating by 180 (flip horizontal and vertical):

Rotate 180:

```
7
   6
      5
         4 3 2
                 1 0
                          RISC-V Bitmanip:
15 14 13 12 11 10 9
                     8
                             rev
23 22 21 20 19 18 17 16
31 30 29 28 27 26 25 24
39 38 37 36 35 34 33 32
                          x86:
47 46 45 44 43 42 41 40
                              14 operations
55 54 53 52 51 50 49 48
63 62 61 60 59 58 57 56
```

#### 4.5.2 Rotating bitboards

Using zip a bitboard can be transposed easily:

#### Transpose:

```
7 15 23 31 39 47 55 63 RISC-V Bitmanip:
6 14 22 30 38 46 54 62 zip, zip, zip
5 13 21 29 37 45 53 61
4 12 20 28 36 44 52 60
3 11 19 27 35 43 51 59 x86:
2 10 18 26 34 42 50 58 18 operations
1 9 17 25 33 41 49 57
0 8 16 24 32 40 48 56
```

A rotation is simply the composition of a flip operation and a transpose operation. This takes 19 operations on x86 [2]. With Bitmanip the rotate operation only takes 4 operations:

#### rotate\_bitboard:

```
rev8 a0, a0
zip a0, a0
zip a0, a0
zip a0, a0
```

#### 4.5.3 Explanation

The bit indices for a 64-bit word are 6 bits wide. Let i[5:0] be the index of a bit in the input, and let i'[5:0] be the index of the same bit after the permutation.

As an example, a rotate left shift by N can be expressed using this notation as  $i'[5:0] = i[5:0] + N \pmod{64}$ .

The GREV operation with shamt N is i'[5:0] = i[5:0] XOR N.

And a SHFL operation corresponds to a rotate left shift by one position of any contiguous region of i[5:0]. For example, zip is a left rotate shift of the entire bit index:

$$i'[5:0] = \{i[4:0], i[5]\}$$

And zip4 performs a left rotate shift on bits 5:2:

$$i'[5:0] = \{i[4:2], i[5], i[1:0]\}$$

In a bitboard, i[2:0] corresponds to the X coordinate of a board position, and i[5:3] corresponds to the Y coordinate.

Therefore flipping the board horizontally is the same as negating bits i [2:0], which is the operation performed by grevi rd, rs, 7 (rev.b).

Likewise flipping the board vertically is done by grevi rd, rs, 56 (rev8).

Finally, transposing corresponds by swapping the lower and upper half of i[5:0], or rotate shifting i[5:0] by 3 positions. This can easily done by rotate shifting the entire i[5:0] by one bit position (zip) three times.

#### 4.5.4 Rotating Bitcubes

Let's define a bitcube as a  $4 \times 4 \times 4$  cube with x = i[1:0], y = i[3:2], and z = i[5:4]. Using the same methods as described above we can easily rotate a bitcube by 90° around the X-, Y-, and Z-axis:

rotate_x:	rotate_y:	rotate_z:				
rev16 a0, a0	rev.n a0, a0	rev4.h

## 4.6 Manipulating 64x64 Bit Matrices

The bmat[x]or and bmatflip instructions operate on 8x8 bit matrices stored in single 64-bit registers, where each byte of such a 64-bit value represents one row (column) of a 8x8 bit matrix.

Let's assume we have a 64x64 bit matrix in memory, stored as one row (column) per 64-bit value. In order to use bmat[x]or and bmatflip on such a matrix, we must first convert it into a 8x8 block matrix of 64 individual 8x8 matrices, each stored in a 64-bit value. The following function performs this transformation for a single row (column) of the block matrix in 40 instructions.

```
void conv8x8(const uint64_t x[8], uint64_t y[8])
 uint64_t x0_x1_31_00 = _rv64_pack (x[0], x[1]);
 uint64_t x2_x3_31_00 = rv64_pack (x[2], x[3]);
 uint64_t x4_x5_31_00 = rv64_pack (x[4], x[5]);
 uint64_t x6_x7_31_00 = rv64_pack (x[6], x[7]);
 uint64_t x0_x1_63_32 = rv64_packu(x[0], x[1]);
 uint64_t x2_x3_63_32 = rv64_packu(x[2], x[3]);
 uint64_t x4_x5_63_32 = rv64_packu(x[4], x[5]);
 uint64_t x6_x7_63_32 = rv64_packu(x[6], x[7]);
 uint64_t x0_x1_31_00_z = _rv64_unzip16(x0_x1_31_00);
 uint64_t x2_x3_31_00_z = rv64_unzip16(x2_x3_31_00);
 uint64_t x4_x5_31_00_z = _rv64_unzip16(x4_x5_31_00);
 uint64_t x6_x7_31_00_z = _rv64_unzip16(x6_x7_31_00);
 uint64_t x0_x1_63_32_z = _rv64_unzip16(x0_x1_63_32);
 uint64_t x2_x3_63_32_z = _rv64_unzip16(x2_x3_63_32);
 uint64_t x4_x5_63_32_z = rv64_unzip16(x4_x5_63_32);
 uint64_t x6_x7_63_32_z = rv64_unzip16(x6_x7_63_32);
 uint64_t x0_x1_x2_x3_15_00 = rv64_pack (x0_x1_31_00_z, x2_x3_31_00_z);
 uint64_t x4_x5_x6_x7_15_00 = rv64_pack (x4_x5_31_00_z, x6_x7_31_00_z);
 uint64_t x0_x1_x2_x3_31_16 = rv64_packu(x0_x1_31_00_z, x2_x3_31_00_z);
 uint64_t x_4x_5x_6x_7_31_16 = rv64_packu(x_4x_5_31_00_z, x_6x_7_31_00_z);
 uint64_t x0_x1_x2_x3_47_32 = rv64_pack (x0_x1_63_32_z, x2_x3_63_32_z);
 uint64_t x4_x5_x6_x7_47_32 = rv64_pack (x4_x5_63_32_z, x6_x7_63_32_z);
 uint64_t x0_x1_x2_x3_63_48 = rv64_packu(x0_x1_63_32_z, x2_x3_63_32_z);
 uint64_t x_4_x_5_6_x_7_6_3_48 = rv64_packu(x_4_x_5_6_3_32_z, x_6_x_7_6_3_32_z);
 uint64_t x0_x1_x2_x3_15_00_z = _rv64_unzip8(x0_x1_x2_x3_15_00);
 uint64_t x4_x5_x6_x7_15_00_z = rv64_unzip8(x4_x5_x6_x7_15_00);
 uint64_t x0_x1_x2_x3_31_16_z = _rv64_unzip8(x0_x1_x2_x3_31_16);
 uint64_t x4_x5_x6_x7_31_16_z = _rv64_unzip8(x4_x5_x6_x7_31_16);
 uint64_t x0_x1_x2_x3_47_32_z = _rv64_unzip8(x0_x1_x2_x3_47_32);
 uint64_t x4_x5_x6_x7_47_32_z = rv64_unzip8(x4_x5_x6_x7_47_32);
 uint64_t x0_x1_x2_x3_63_48_z = _rv64_unzip8(x0_x1_x2_x3_63_48);
 uint64_t x4_x5_x6_x7_63_48_z = rv64_unzip8(x4_x5_x6_x7_63_48);
 y[0] = rv64_pack (x0_x1_x2_x3_15_00_z, x4_x5_x6_x7_15_00_z);
 y[1] = rv64_packu(x0_x1_x2_x3_15_00_z, x4_x5_x6_x7_15_00_z);
 y[2] = rv64_pack (x0_x1_x2_x3_31_16_z, x4_x5_x6_x7_31_16_z);
 y[3] = rv64_packu(x0_x1_x2_x3_31_16_z, x4_x5_x6_x7_31_16_z);
 y[4] = rv64_pack (x0_x1_x2_x3_47_32_z, x4_x5_x6_x7_47_32_z);
 y[5] = rv64_packu(x0_x1_x2_x3_47_32_z, x4_x5_x6_x7_47_32_z);
 y[6] = rv64_pack (x0_x1_x2_x3_63_48_z, x4_x5_x6_x7_63_48_z);
 y[7] = rv64_packu(x0_x1_x2_x3_63_48_z, x4_x5_x6_x7_63_48_z);
```

Each of the 5 blocks in this function only consumes the eight outputs of the previous block. Therefore 16 registers are sufficient to run this function in registers only without the need to spill any

data on the stack.

Note that this function is its own inverse. Therefore the same function can be used for the convertion from block matrix form back to row (column) major form.

A bit 64x64 bit matrix in block matrix form can easily be transposed by running bmatflip (or zip; zip; zip) on the blocks of the matrix and then renaming the individual 64-bit variables.

To multiply 64x64 bit matrices in block matrix form, the matrix-matrix-product is decomposed in the obvious way in  $8 \times 8 \times 8 = 512$  bmat [x] or instructions and  $7 \times 8 \times 8 = 448$  [x] or instructions.

## 4.7 Inverting Xorshift RNGs

Xorshift RNGs are a class of fast RNGs for different bit widths. There are 648 Xorshift RNGs for 32 bits, but this is the one that the author of the original Xorshift RNG paper recommends. [18, p. 4]

```
uint32_t xorshift32(uint32_t x)
{
    x ^= x << 13;
    x ^= x >> 17;
    x ^= x << 5;
    return x;
}</pre>
```

This function of course has been designed and selected so it's efficient, even without special bitmanipulation instructions. So let's look at the inverse instead. First, the naïve form of inverting this function:

```
uint32_t xorshift32_inv(uint32_t x)
{
   uint32_t t;
   t = x ^ (x << 5);
   t = x ^ (t << 5);
   t = x ^ (t << 5);
   t = x ^ (t << 5);
   t = x ^ (t << 5);
   t = x ^ (t << 5);
   t = x ^ (t << 5);
   x = x ^ (t << 5);
   x = x ^ (t << 5);
   x = x ^ (t << 5);
   x = x ^ (t << 13);
   x = x ^ (t << 13);
   return x;
}</pre>
```

This translates to 18 RISC-V instructions, not including the function call overhead.

Obviously the C expression x (x >> 17) is already its own inverse (because  $17 \ge XLEN/2$ ) and therefore already has an effecient inverse. But the two other blocks can easily be implemented using a single clmul instruction each:

```
uint32_t xorshift32_inv(uint32_t x)
{
    x = clmul(x, 0x42108421);
    x = x ^ (x >> 17);
    x = clmul(x, 0x04002001);
    return x;
}
```

This are 8 RISC-V instructions, including 4 instructions for loading the constants, but not including the function call overhead.

An optimizing compiler could easily generate the clmul instructions and the magic constants from the C code for the naïve implementation. (0x04002001 = (1 << 2\*13) | (1 << 13) | 1 and 0x42108421 = (1 << 6\*5) | (1 << 5\*5) | ... | (1 << 5) | 1)

The obvious remaining question is "if clmul(x, 0x42108421) is the inverse of x ^ (x << 5), what's the inverse of x ^ (x >> 5)?" It's clmulr(x, 0x84210842), where 0x84210842 is the bit-reversal of 0x42108421.

A special case of xorshift is  $x ^ (x >> 1)$ , which is a gray encoder. The corresponding gray decoder is clmulr(x, 0xffffffff).

## 4.8 Cyclic redundency checks (CRC)

There are special instructions for performing CRCs using the two most widespread 32-bit CRC polynomials, CRC-32 and CRC-32C.

CRCs with other polynomials can be computed efficiently using CLMUL. The following examples are using CRC32Q.

The easiest way of implementing CRC32Q with clmul is using a Barrett reduction. On RV32:

```
uint32_t crc32q_simple(const uint32_t *data, int length)
{
   uint32_t P = 0x814141AB; // CRC polynomial (implicit x^32)
   uint32_t mu = 0xFEFF7F62; // x^64 divided by CRC polynomial
   uint32_t mu1 = 0xFF7FBFB1; // "mu" with leading 1, shifted right by 1 bit
   uint32_t crc = 0;

for (int i = 0; i < length; i++) {
   crc ^= rev8(data[i]);
   crc = clmulr(crc, mu1);
   crc = clmul(crc, P);
}

return crc;
}</pre>
```

The following python code calculates the value of mu for a given CRC polynomial:

```
def polydiv(dividend, divisor):
      quotient = 0
      while dividend.bit_length() >= divisor.bit_length():
          i = dividend.bit_length() - divisor.bit_length()
          dividend = dividend ^ (divisor << i)</pre>
          quotient |= 1 << i
      return quotient
 P = 0x1814141AB
 print("0x%X" % (polydiv(1<<64, P))) # prints 0x1FEFF7F62</pre>
A more efficient method would be the following, which processes 64-bit at a time (RV64):
  uint32_t crc32q_fast(const uint64_t *p, int len)
    uint64_t P = 0x1814141ABLL; // CRC polynomial
    uint64_t k1 = 0xA1FA6BECLL; // remainder of x^128 divided by CRC polynomial
    uint64_t k2 = 0x9BE9878FLL; // remainder of x^96 divided by CRC polynomial
    uint64_t k3 = 0xB1EFC5F6LL; // remainder of x^64 divided by CRC polynomial
    uint64_t mu = 0x1FEFF7F62LL; // x^64 divided by CRC polynomial
    uint64_t a0, a1, a2, t1, t2;
    assert(len >= 2);
    a0 = rev8(p[0]);
    a1 = rev8(p[1]);
    // Main loop: Reduce to 2x 64 bits
    for (const uint64_t *t0 = p+2; t0 != p+len; t0++)
    {
     a2 = rev8(*t0);
     t1 = clmulh(a0, k1);
     t2 = clmul(a0, k1);
     a0 = a1 ^t1;
     a1 = a2 ^t2;
    // Reduce to 64 bit, add 32 bit zero padding
    t1 = clmulh(a0, k2);
    t2 = clmul(a0, k2);
    a0 = (a1 >> 32) ^ t1;
    a1 = (a1 << 32) ^ t2;
    t2 = clmul(a0, k3);
    a1 = a1 ^t2;
```

```
// Barrett Reduction

t1 = clmul(a1 >> 32, mu);
t2 = clmul(t1 >> 32, P);
a0 = a1 ^ t2;

return a0;
}
```

The main idea is to transform an array of arbitrary length to an array with the same CRC that's only two 64-bit elements long. (That's the "Main loop" portion of above code.)

Then we further reduce it to just 64-bit. And then we use a Barrett reduction to get the final 32-bit result.

The following python code can be used to calculate the "magic constants" k1, k2, and k3:

```
def polymod(dividend, divisor):
    quotient = 0
    while dividend.bit_length() >= divisor.bit_length():
        i = dividend.bit_length() - divisor.bit_length()
        dividend = dividend ^ (divisor << i)
        quotient |= 1 << i
        return dividend

print("0x%X" % (polymod(1<<128, P))) # prints 0xA1FA6BEC
print("0x%X" % (polymod(1<< 96, P))) # prints 0x9BE9878F
print("0x%X" % (polymod(1<< 64, P))) # prints 0xB1EFC5F6</pre>
```

The above example code is taken from [26]. A more detailed descriptions of the algorithms employed can be found in [11].

## 4.9 Decoding RISC-V Immediates

The following code snippets decode and sign-extend the immediate from RISC-V S-type, B-type, J-type, and CJ-type instructions. They are nice "nothing up my sleeve"-examples for real-world bit permutations.

31   27   26   25   24	20   19	15	14 12	11 7	6 0	
imm[11:5]				imm[4:0]		S-type
imm[12 10:5]				imm[4:1 11]		B-type
imm[20 10:	1 11 19:12]					J-type

	15	14	13	12	11	10	9	8	7	6	5	4	3		-	
Γ					i	mm	[11	4 9	:8 10	0 6 '	7 3:1	1[5]				CJ-type

```
decode_s:
                                           // variant 2 (without RISC-V Bitmanip)
  li t0, 0xfe000f80
                                           decode_cj:
  bext a0, a0, t0

# Change History

Date	Rev	Changes
2017-07-17	0.10	Initial Draft
2017-11-02	0.11	Remove roli, assembler can convert it to use a rori
		Remove bitwise subset and replace with andc
		Doc source text same base for study and spec.
		Fix typos
2017-11-30	0.32	Jump rev number to be on par with associated Study
		Move pdep/pext into spec draft and called it scatter-gather
2018-04-07	0.33	Move to github, throw out study, convert from .md to .tex
		Fix typos and fix some reference C implementations
		Rename bgat/bsca to bext/bdep
		Remove post-add immediate from clz
		Clean up encoding tables and code sections
2018-04-20	0.34	Add GREV, CTZ, and compressed instructions
		Restructure document: Move discussions to extra sections
		Add FAQ, add analysis of used encoding space
		Add Pseudo-Ops, Macros, Algorithms
		Add Generalized Bit Permutations (shuffle)
2018-05-12	0.35	Replace shuffle with generalized zip (gzip)
		Add additional XBitfield ISA Extension
		Add figures and tables, Clean up document
		Extend discussion and evaluation chapters
		Add Verilog reference implementations
		Add fast C reference implementations

Date	Rev	Changes
2018-10-05	0.36	XBitfield is now a proper extension proposal
		Add bswaps. [hwd] instructions
		Add cmix, cmov, fsl, fsr
		Rename gzip to shfl/unshfl
		$\operatorname{Add}$ min, max, minu, maxu
		Add clri, maki, join
		Add cseln, cselz, mvnez, mveqz
		Add clmul, clmulh, bmatxor, bmator, bmatflip
		Remove bswaps.[hwd], clri, maki, join
		Remove cseln, cselz, mvnez, mveqz
2019-06-10	0.90	Add dedicated CRC instructions
		Add proposed opcode encodings
		Rename from XBitmanip to RISC-V Bitmanip
		Remove chapter on bfxp[c] instruction
		Refactor proposal into one big chapter
		Remove c.brev and c.neg instructions
		Add fsri, pack, addiwu, slliu.w
		Add addwu, subwu, addu.w, subu.w
		Rename andc to andn, Add orn and xnor
		Add sbset[i], sbclr[i], sbinv[i], sbext[i]
		New naming scheme for grevi pseudo-ops
		Add clmulr instruction (reversed clmul)
		Jump to Rev 0.90 to indicate spec matureness
2019-08-29	0.91	Change encodings of bmatxor and grev[i][w]
		Add gorc[i][w] and bfp[w] instructions
????-??-??	0.92	Add packh and packu[w] instructions
